Malingering of general dissociative amnesia with/without fugue may occur in individuals who are attempting to avoid consequences of legal, financial, or personal difficulties and in soldiers attempting to avoid combat or unpleasant military duties. These precipitating factors may be present as well in bona fide dissociative amnesia/fugue (see above). In the forensic context, the examiner should always consider the diagnosis of malingering when dissociative amnesia/fugue is claimed. On the other hand, factitious forms of dissociative amnesia often resemble the CAMD clinical picture. This may be related to wishing to seem a more interesting patient and/or adopting the imitative role of a childhood trauma survivor, or that of a more severely harmed trauma survivor. In some complex cases both genuine and exaggerated amnesia/fugue may be reported. For example, a woman with dissociative identity disorder feigned experiencing a several-day dissociative fugue after reported revictimization by a childhood abuser. As discrepancies in her story emerged, she admitted that she had spent the weekend with a new lover, betraying her long-term partner and frightening her outpatient therapist.

On the other hand, in clinical case reports, many malingerers have quickly confessed their deceptions spontaneously or when confronted by an examiner. In these nonforensic reports, the malingered amnesiacs were frequently pathetic individuals whose deception was transparent. Nevertheless, it can often be unclear where the conscious deception began and the unconscious defenses ended. In forensic contexts, feigned dissociative amnesia often is conveniently located for events related to criminal behavior but not to other areas of life. Feigners may become angry and resistant when their memory issues are challenged. They may claim amnesia for some circumstances where their responsibility is at issue yet appear to have detailed recall of events and people with whom they are displeased and from whom they wish to extract some form of gain.

Bethany Brand and colleagues have developed psychological assessment batteries to attempt to discriminate feigned from genuine dissociative disorders and from dissociative disorders with factitious/malingered exaggeration. These may include standard screening and diagnostic inventories for dissociative disorders, personality assessment, MMPI, Rorschach, other measures to assess trauma history, PTSD, and complex trauma, as well measures used in forensic assessment of feigning (e.g., SIRS-II, TOMM). She and her colleagues have demonstrated that patients with actual dissociative disorder may be misclassified on some forensic measures for feigning. Interpretation of findings may require a psychologist with extensive clinical and assessment experience with dissociative disorders.

A patient who presents to psychiatric attention asking to “recover repressed memories” as a chief complaint is most likely to have a factitious disorder, and may display factitious or the imitative form of dissociative identity disorder described in prior sections. Most of these individuals do not describe bona fide amnesia when carefully questioned but they are often insistent that they must have been abused—or more extensively abused—in childhood to explain their unhappiness or life dysfunction. Unlike feigners, most dissociative individuals are fearful, ashamed, and avoidant of recall of traumatic memories and minimize and deny the dissociative amnesia and trauma history, even when corroborated. Memory recall in dissociative amnesia does not present as typical episodic, autobiographical memory recall. Rather, these usually are experienced as disturbing intrusive flashbacks with alarming and vivid perceptual, somatoform, and emotional experiences. They may display freezing or agitation, often with defensive dissociative symptoms like depersonalization/derealization, trance states, and attempts to “re-dissociate” the material.

Clinical Course and Prognosis

Little is known about the clinical course of dissociative amnesia. Acute dissociative amnesia can resolve spontaneously once the person is removed to safety from traumatic or overwhelming circumstances. At the other extreme, many patients develop chronic forms of generalized, continuous, or severe localized amnesia who may be so profoundly disabled to require social support, such as nursing home placement or intensive family caretaking.

Individuals with nonclassic dissociative amnesia may have a persistent form of the disorder that does not cause them overt distress and thus may not seek clinical attention. Some of these individuals can be understood as being in an episode of PTSD characterized primarily by avoidant symptoms. In some cases, a later traumatic event or stress—even a relatively minor one—precipitates a florid episode of PTSD with alternations of re-experiencing and avoidant or amnestic symptoms.

Studies have shown that recall of previously dissociated memory frequently occurs outside of therapeutic settings, triggered by a variety of stimuli, including the person's children reaching a specific age at which the individual was abused, abuse of their own children, media accounts of trauma or abuse, death of an abusive parent, a variety of sensory cues, and feeling safe enough from danger in one's life situation, among others. Meta-analytic studies show that there is no difference in accuracy of trauma memory with delayed recall compared with "continuous" trauma memory.

Treatment

The diagnosis and treatment of dissociative amnesia became controversial in the 1990s due to disputes, often in the media and the courts, over delayed recall of childhood sexual abuse (see section on History of Dissociation). Prior to this, dissociative (psychogenic) amnesia and delayed recall for combat or other forms of trauma had not been considered controversial, even written about by clinician/researchers who later claimed it could not occur. Authors from the World War I and II eras opined that some of these wartime cases were malingered. In this regard, particularly during and after World War I, punitive treatments such as electric shock were devised for wartime amnesia and conversion symptoms. Also, controversy exists not only for the existence of dissociative amnesia but also for how to treat it.

Critics of the dissociative amnesia construct invented a false, nonexistent treatment: *recovered memory therapy* (RMT) to characterize a procedure in which clinicians supposedly make aggressive efforts and pressure patients to recall reported hidden, long-forgotten traumas as the central focus of treatment. RMT does not represent a known school of therapy or of scholarly research. It may more accurately describe individual fringe practitioners and/or media or layperson views of trauma treatment.

The controversy over delayed recall of childhood sexual abuse is often discussed as if the clinical situation involves forensic determination of the “truth” of “accusations.” Episodic, autobiographical memory is adaptive, not forensic. The gist of trauma memory is more likely accurate than peripheral details. In most circumstances, clinicians do not “validate” information patients report in treatment (e.g., where they were born, who was in their family, where they live, etc.) Barring extensive documentation that may include perpetrator admissions, documented physical injuries, etc., the clinician must realize that they “were not there” to determine the “truth” of maltreatment reports. Traumatized patients often vacillate between recalling childhood maltreatment (e.g., “I know this happened to me”) and discounting their recollections (e.g., “I’m a liar, I made it all up”). As discussed in the section on dissociative identity disorder, just as in any other psychotherapy, the clinician’s role is to assist the patient in making sense of their autobiography, not to make a forensic determination. This allows patients to explore issues like screen memories, viewing events differently from a more integrated perspective, and/or becoming increasingly clear that they accurately recall experiencing maltreatment during childhood. Clinicians find that it is more common that traumatized patients struggle, not with trauma “accusations,” but with attachment to abusive caregivers, associated with dogged rationalization of or self-blame for maltreatment. Thus, reviews of the literature on trauma treatment emphasize that the predominant model for work on traumatic memories involves a focus on symptom stabilization and safety, integration of posttraumatic memories, beliefs, cognitions, affects, somatic representations, and object relations, not on memory recall as an end in itself.

Phase-Oriented Treatment. As for dissociative identity disorder, phase-oriented treatment is the current standard of care for the treatment of dissociative amnesia, although there are no systematic studies with large cohorts of patients. Treatment of the patient with acute, classic dissociative amnesia follows a similar phasic model. However, here, memory recall is a central issue, because loss of memory for personal identity and/or dense deletions in autobiographical memory is disabling and requires rapid intervention. On the other hand, case series of patients with generalized dissociative amnesia document serious suicide attempts and even death by suicide when amnestic barriers are removed precipitously without adequate preparation and patient stabilization. Clinicians should make sure that they and the patient are both prepared for the abreaction of extreme emotions (e.g., terror, rage, extreme shame), that accompany recollection of devastating traumatic experiences and/or extreme psychological conflict.

Safety in Acute Stress Disorder with Dissociative Amnesia. Studies of psychiatric combat casualties with acute dissociative amnesia—with or without fugue—provide useful practical principles for treating ASD with dissociative amnesia. Acute generalized dissociative amnesia/fugue may occur in civilian settings during natural disasters, mass casualty events, refugees exposed to terrorism, torture, and civilians affected by war with/without refugee status. Unfortunately, in many of the latter circumstances, resources for medical, let alone psychiatric, care are minimal. In refugee populations, individuals may suffer from additional physical and sexual violence and exploitation, be grieving over the violent deaths of relatives, and lack basic provision of food, water, clothing, housing, or sanitation.

To the extent possible, establishing the person's physical safety is the first concern. This involves removing the individual from the traumatizing environment (e.g., acute combat), evaluating and treating medical problems, and providing shelter, food, and the ability to sleep. The paradigm of *psychological first aid* may be helpful in the initial stabilization of the acutely traumatized, amnesic individual. Sedative medications, such as the benzodiazepines, may be indicated to assist the patient with sleep. Case series suggest that, in this acute context, many patients with acute amnesia may have a relatively rapid spontaneous remission of symptoms once brought to the safety of the hospital or other protected environment (e.g., removal from the battlefield, provision of sleep). If immediate spontaneous remission does not occur after removal from traumatic environments, symptoms may abate later simply during the clinician's taking a psychiatric history or merely with suggestions and reassurance.

Phasic Treatment. As described in the section on dissociative identity disorder, three basic phases are recognized for treatment of both types of dissociative amnesia. This structure is heuristic to some extent because aspects of each phase may be worked on during another. First, there is a stabilization phase, with a focus on safety, symptom control, containment of affects and impulses, and education about trauma treatment. Once adequate personal safety and clinical stability are established, if indicated, the individual may engage in a second phase that focuses on the integration of traumatic material in greater depth. This processing may involve attempts to gently interpret the fear that may underlie ongoing amnesia and to resolve material that is not dissociated or less completely dissociated. Finally, there is a third phase of *resolution* or *reintegration* in which the traumatized person is reconnected to ordinary life. In this phase, the focus is less on the trauma per se and more on the development of a renewed, reinvigorated life that overcomes the lack of freedom imposed by symptoms of the trauma disorder and the dominance of the person's psychology by issues related to traumatization.

In general, studies of treatment outcome in survivors of rape and childhood sexual abuse have shown better outcome when patients directly discuss dissociated trauma material in the context of a carefully designed, physically structured individual or group psychotherapy. International studies of individuals in specialized treatment for childhood sexual abuse show that dissociative trauma survivors do not improve without a direct focus on dissociation.

Safety in Nonclassic Dissociative Amnesia. Patients with nonclassic amnesia presentations generally should be managed within the framework of a longer-term psychotherapy directed at resolving the complex psychological sequelae of severe traumatization due to childhood maltreatment, combat, rape, intimate partner violence, trafficking, and/or other forms of adult victimization. Here, too, the first tasks of treatment are restoration of the patient's physical well-being and safety and establishment of a therapeutic alliance. The clinician must be prepared to intervene actively if the patient is acutely dangerous to self or others. Typically, these patients' difficulties involve suicide attempts, nonsuicidal self-injury, eating disorders, high-risk behaviors (e.g., reckless driving), alcohol or substance abuse, involvement in abusive or destructive relationships, episodes of rage or violence, abuse of the individual's own children or family members, and lack of adequate food, clothing, or shelter. Hospitalization may be necessary for stabilization, as may referral to specialty resources such as treatment for substance abuse or eating disorders.

In individuals with severe intrusive PTSD symptoms alternating with amnesia, containment, and management of intrusive recollections rather than detailed processing of the traumatic material are usually the main goals of the stabilization phase of treatment. This may be accomplished with supportive psychotherapy, pharmacotherapy, imagery or hypnotic techniques for containment and symptom control, and/or dialectical behavioral and cognitive therapy techniques, or a combination of these. Although there is no pharmacologic agent that specifically targets dissociative amnesia, specific psychopharmacological treatment of the patient’s PTSD, mood, impulsive, psychotic, obsessive-compulsive, or anxiety symptoms may help stabilize severe symptoms that prevent the patient’s meaningful participation in psychotherapy.

Long-term treatment for these patients is focused on the manifold dimensions of dysfunction that chronic trauma engenders. These include problems with emotional, mood, anxiety, and impulse regulation; disordered attachment schemas engendering troubled relationships and problems with interpersonal boundaries; spontaneous altered states of consciousness and dissociation; memory problems; cognitive distortions and disordered meaning systems; perceptual abnormalities; problems with the sense of self and body image; somatoform symptoms; and self-destructiveness.

Treatment of Amnesia. Treatment of patients with nonclassic forms of dissociative amnesia necessitates that, to provide ongoing informed consent, the clinician should familiarize themselves with the controversies about trauma and memory, as well as the standard of care for phasic treatment. Factors that usually contraindicate intensive memory integration work are listed in Table 20–22 (see also Table 20–23 in the section on Dissociative Identity Disorder).

Free Recall. Patients with both forms of dissociative amnesia may respond well to free-recall strategies in which they allow memory material to enter consciousness. The clinician is supportive and nondirective but focuses on conflict, psychological defenses, and/or conscious reluctance to free recall to take place. Classic free-association suggestions are often the most helpful in understanding factors that interfere with recall and in allowing recall to occur at a pace that the patient can tolerate. Authorities recommend that in all trauma processing work, to the extent possible, the clinician not ask leading questions, whether in a free-recall situation or with methods that facilitate memory recall (see below). This includes statements like, “what happened then?,” “what happened next?,” or “what did you think/feel at the time?” When exploring posttraumatic cognitive distortions like unwarranted self-blame and shame for aspects of the traumatic experiences, the clinician can inquire about what led to these beliefs, what would the person think if someone else described similar reactions in a traumatic context, and so on. These strategies gently challenge posttraumatic cognitive distortions. In general, it is most helpful to recontextualize these beliefs by locating them within the emerging history, as the patient may experience the all-too-common posttraumatic schema that self-blame is preferable to the experience of utter helplessness at the core of most traumatic experiences. Distress at recall may be titrated by techniques for distancing and fractioning emotion. For example, the patient may be asked to give a brief “headline” or two, as if reading a newspaper, but not to go into more detail (e.g., reading the newspaper article in full) until better able to do so.

Transference Interpretations. Studies of transference in patients with combat-related PTSD and severe dissociative disorders indicate that a traumatic transference is usually the predominant transference theme in these individuals. This is a set of unconscious perceptions of the clinician based on relationships formed under traumatic circumstances. For instance, the therapist becomes the buddy who was killed next to the patient in battle, the persecutory abusive parent, the incompetent officer who sent the patient into battlefield disaster, the neglectful relative unconcerned about the patient’s abuse, or the patient themselves who is subject to the sadistic, abusive behaviors of an implacable other. Identification of the overt patterns of traumatic transference observed by the therapist may be another route to undoing amnesia. A recent study of corroborated trauma memory found that transference-based recall was more accurate than other forms of facilitated recall.

Cognitive Therapy. Cognitive therapy may have specific benefits for individuals with trauma disorders. Identifying the specific cognitive distortions that are based in the trauma may also provide an entrée into autobiographical memory for which the patient experiences amnesia. As the patient is more able to correct cognitive distortions, particularly about the meaning of prior trauma, more detailed recall of traumatic events may occur, although the potential for flooding is a significant concern. Educating patients about the concept of hindsight bias may be helpful. Here, later information biases understanding of events as they unfolded in real time (e.g., the “Monday morning quarterback”). In posttraumatic disorders, hindsight bias is invariably *negative*, with shame, self-blame, and survivor guilt for what occurred.

Facilitated Recall of Trauma Material. A hierarchy of techniques to facilitate recall has been described for dissociative amnesia. The techniques include: (1) context reinstatement (i.e., attempts to focus the patient on time periods for surrounding the amnesia); (2) state-dependent recall (i.e., intensification and focus on affects or somatic sensations that appear to be related to trauma, such as terror, horror, confusion, rage, or sudden nausea or dizziness); and (3) specialized adjunctive techniques (e.g., hypnosis, relaxation, imagery, pharmacologically assisted interviews). Each of these techniques may facilitate recall of dissociated memories, particularly in classic forms of dissociative amnesia. It is particularly important that, when implementing these techniques, to the extent possible, the clinician use nonleading, nonsuggestive questions to minimize concern about inaccurate or confabulated recall. Some nonclinical research studies suggest that techniques for facilitation of recall may increase inaccurate recall. This remains a complex topic in terms of the ecologic validity of this research to treatment of traumatized individuals; what aspects of recall may be inaccurate (e.g., peripheral details vs. central aspects of the narrative), and what factors induce the inaccuracy (e.g., the techniques themselves or more general expectations and demand characteristics, such as hypnosis is somehow “special” in evoking accurate memories). The clinician’s overall stance about trauma treatment and approach to trauma memory is most important in managing these issues.

Hypnosis for Amnesia. Hypnosis has frequently played an important adjunctive role in the treatment of individuals with dissociative amnesia and dissociative fugue. Hypnosis is not a treatment in itself; rather, it is a set of adjunctive techniques that facilitate certain psychotherapeutic goals. The construct of hypnosis encompasses a wide and complex domain of phenomena and responses that have been applied to many therapies and diverse individuals. Concern about inaccuracies in hypnotically facilitated recall is based on research on memory for nontraumatic information showing that hypnosis increases a person’s confidence in what is recalled, even if it is erroneous. However, critical reviews have noted the complexity of this research problem, the inconsistency of findings among studies, and the many variables related to hypnosis and nonhypnotic factors that appear to influence this and related phenomena. These reviews have emphasized that memory confabulation is related to techniques of social influence on suggestible subjects rather than to hypnosis per se.

The use of hypnosis for memory recall in no way ensures the veracity, or lack of veracity, of the information produced. The clinician should be aware of the reconstructive nature of memory and should avoid suggestions to the contrary. Thus, in addition to obtaining the patient's informed consent for the use of hypnosis, it is currently considered prudent to also obtain informed consent concerning the reliability or possible lack thereof for autobiographical information revealed during hypnosis. Studies show that educating patients about the controversies regarding hypnosis and memory and informing them of the need to critically evaluate any memory material that they recall during hypnosis, or at any other time in treatment, reduces the likelihood of credulous acceptance of potentially inaccurate information.

Also, clinicians should be aware that, in some states of the United States, individuals who have been exposed to therapeutic hypnosis might be enjoined from giving testimony as a witness in court. This may be so even if the hypnosis had little relationship to the events at legal issue. The clinician should attempt to discuss fully these issues with the patient and their legal counsel.

Hypnosis can be used in several different ways in the treatment of dissociative amnesia. Hypnotic interventions can contain, modulate, and titrate the intensity of symptoms; facilitate controlled recall of dissociated memories; provide support and ego strengthening for the patient; and, finally, promote working through and integration of dissociated material. In addition, the patient can be taught self-hypnosis to apply containment and calming techniques in their everyday life. Successful use of containment techniques, whether hypnotically facilitated or not, also increases the patient's sense that they can more effectively be in control of alternations between intrusive symptoms and amnesia.

In the acutely amnestic patient, a few sessions to help the patient experience trance successfully and to explore containment and distancing techniques may be sufficient to allow focused hypnotic work on the material for which the patient is amnestic. Clinicians since World War I have recognized how valuable it is for patients to process dissociated material repeatedly over several sessions, often at different levels of affective intensity, to complete the process of integrating the material. In cases of acute amnesia, the first session for memory processing may necessarily be explorative. Here, again, the initial goal is to gain an overview of the information for which the patient is amnesic. As in cases of chronic amnesia, subsequent sessions then focus on reworking the material in greater detail. However, in nonclassic cases of severe, longstanding, posttraumatic disorders, the amnesia itself should be addressed only gradually in the context of a longer-term psychotherapy in which life stability and function are the basic foci.

It is useful to try to account systematically for different dimensions of the traumatic experience—sensory, affective, cognitive, and behavioral—to ensure that all key components have been identified and reconstructed. It is also useful to attempt to account systematically for a variety of painful affects that are commonly experienced during traumatic experiences such as despair, sorrow, grief, horror, shame, helplessness, rage, guilt, confusion, and anguish. Not all of these may be present in each patient; however, it is useful for the clinician to keep track of which affects the patient most readily describes and which seem less available. Inquiry about these other affects may be quite helpful in resolving the amnesia. Shame, horror, helplessness, and overwhelming confusion are emotions that patients may have the most trouble identifying without assistance from the therapist.

The treatment process is similar when the acute amnesia results not from traumatic experiences but from aspects of the person’s current behavior that conflict with deeply held moral values or behavioral standards. In these instances, treatment initially seeks to help the patient tolerate these affects and conflicts without resorting to dissociative defenses. Frequently, these patients describe a developmental history characterized by a rigid family moral code enforced with harsh physical discipline. These experiences often appear to be the traumatic underpinning of the dissociative diathesis. Psychotherapy and hypnotherapy in these patients are directed in part at reducing the patient’s brutally unreasonable, and often conflicting, expectations of themselves and the guilt and shame that so often accompany acute dissociation. Furthermore, these patients may have great difficulty tolerating anger or violent impulses because such affects tend to trigger recall of earlier experiences with physical abuse or similar traumas, often as a flashback experience. Thus, psychotherapy may serve not only to focus on the conflicts that led to the acute amnesia but also to explicate and work through the patient's thoughts, feelings, and self-perceptions related to the antecedent traumatic events.

Somatic Therapies. There is no known pharmacotherapy for dissociative amnesia other than pharmacologically facilitated interviews. A variety of agents have been used for this purpose, including sodium amobarbital, thiopental (Pentothal), oral benzodiazepines, and amphetamines. To date, no controlled studies have assessed the efficacy of any of these agents in comparison with one another or with other treatment methods. A single placebo-controlled study of a barbiturate-facilitated interview did not find superiority of sodium amobarbital over placebo in producing more clinically useful information. In more systematic World War II studies of barbiturate-facilitated interviews for amnesia and conversion disorder, this treatment was described as producing more rapid recovery, especially for amnesia, although little overall difference was found in recovery in comparison to subjects treated with psychotherapy alone or with hypnotherapy.

Amobarbital narcosynthesis is a term devised to underscore the need for the patient to process material uncovered in a pharmacologically facilitated interview in their usual conscious state. Pharmacologically facilitated interviews are used primarily with acute amnesias and conversion disorder, among other indications, in general hospital medical and psychiatric services. This procedure is also occasionally useful in refractory cases of chronic dissociative amnesia when patients are unresponsive to other interventions. The Joint Commission now considers pharmacologically facilitated interviews to be conscious sedation, requiring the presence of an anesthesiologist. This procedure must be performed in settings where resuscitation equipment is available in case of respiratory arrest, a possible, albeit rare, complication. The interview usually is audiotaped or videotaped to replay for the patient, because amnesia generally is present for the material produced. Although in some cases repeated procedures may be helpful, in others, repeated procedures have led to the patient's dependence on pharmacologically facilitated interviews.

The current controversies over delayed recall for trauma have also focused on the use of pharmacologically facilitated interviews for patients with reported amnesia for childhood maltreatment. No modern systematic data exist on memory fallibility or accuracy in individuals undergoing pharmacologically facilitated interviews. As discussed previously, pharmacologically facilitated interviews were used extensively in World

War II for the treatment of combat-related dissociation. Although wartime memories recovered with pharmacologically facilitated interviews were generally considered to be accurate, some subjects were reported to dissemble completely or withhold crucial information, or both, despite barbiturate treatment.

Given the current controversies, the clinician should obtain informed consent focusing on the nature of memory for pharmacologically facilitated interviews for amnesia as for patients considering hypnosis. The clinician should emphasize that these drugs are not a truth serum; whatever apparently new information emerges under the drug condition should be regarded no differently with respect to accuracy than any other material that emerges over the course of treatment.

Group Psychotherapy for Amnesia. During World War II, group psychotherapy and group hypnotherapy were among the treatments used to promote recovery in traumatic war-related amnesia. Highly supportive, structured, reassuring, and re-educative approaches were often used by therapists in such cases to accomplish return of the patient to functional status and to prevent chronic disability.

Time-limited and longer-term group psychotherapies have been reported to be helpful for combat veterans with PTSD and for survivors of childhood abuse. During group sessions, some authors report that patients recall memories for which they have had amnesia. Supportive interventions by the group members or the group therapist, or both, may facilitate integration and mastery of the dissociated material. On the other hand, concern has been raised about memory contamination in such group therapy settings, as it has for patients' involvement in 12-step or self-help groups for trauma survivors.

TREATMENT OF DISSOCIATIVE FUGUE SUBTYPE. Treatment for dissociative fugue follows the basic structure described above for treatment of dissociative amnesia. Once stabilization is achieved, subsequent therapy is focused on helping the patient regain memory for identity, life circumstances, and personal history. Some patients with dissociative fugue may resist uncovering their actual identity even with hypnosis or pharmacologically assisted interviews. Appeals through the local (sometimes regional, national, or international) media may not alert the patient's concerned others. In one case, a patient was asked to randomly select numbers on a phone keypad. The patient tapped a phone number—

apparently outside of conscious awareness—that allowed the treating clinician to find the patient’s family hundreds of miles away.

Family, sexual, occupational, or legal problems that were part of the original matrix that generated the fugue episode may be substantially exacerbated by the time the patient’s original identity and life situation are detected. Thus, family treatment, legal, and social service assistance may be necessary to help resolve such complex difficulties. Also, the patient may display other extreme or bizarre dissociative symptoms, such as the Ganser symptom of approximate answers, or attempt to engage in another fugue to escape the situation.

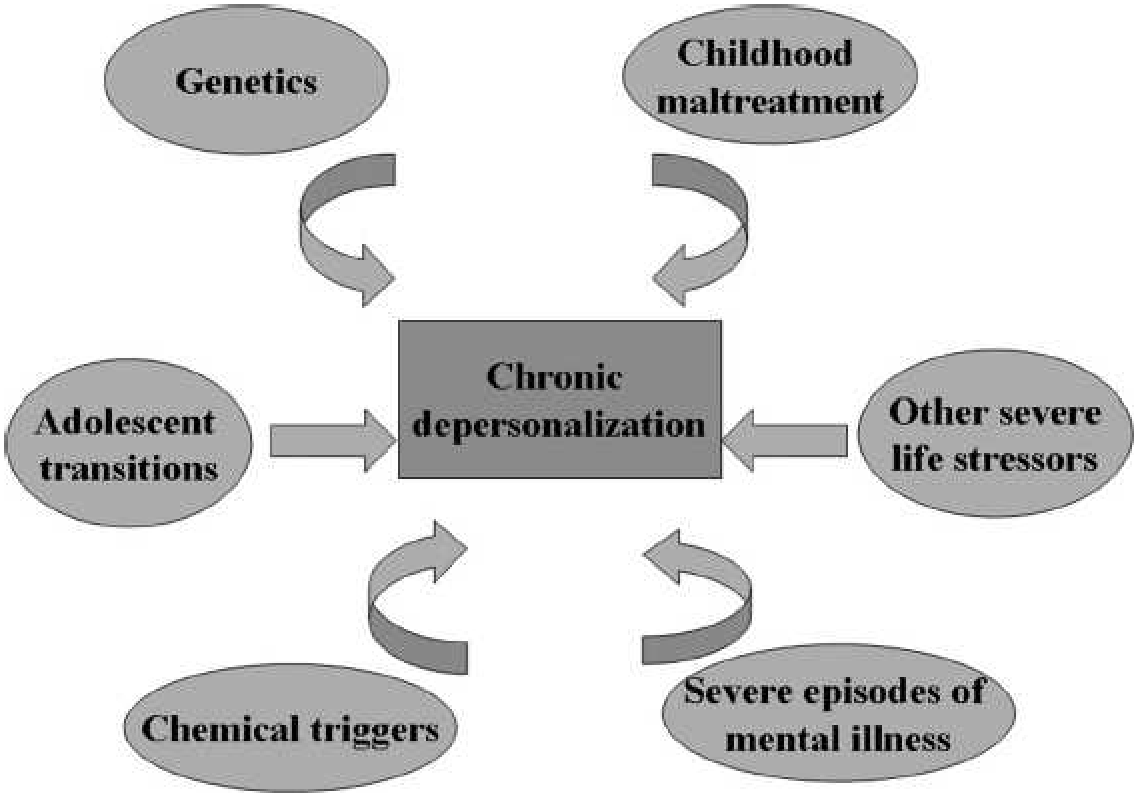
DEPERSONALIZATION/DEREALIZATION DISORDER

As described in the section on Nosology, the DSM-IV-TR diagnosis of depersonalization disorder was renamed depersonalization/derealization disorder in DSM-5. This was based on a review that found no differences between patients with predominant depersonalization and those with predominant derealization, confirming the ICD-10/11 conceptualization of either symptom as characteristic of the disorder.

For many years, the ubiquity of depersonalization/derealization as a psychiatric symptom obscured its broader recognition as a disorder. Consequently, patients with chronic and primary depersonalization/derealization are commonly misdiagnosed as having solely mood or anxiety disorders. These disorders may be comorbid with chronic depersonalization/derealization and/or may develop in response to untreated depersonalization/derealization disorder symptoms. Recent systematic research by Daphne Simeon and Anthony David on two large cohorts of well-characterized patients with depersonalization/derealization disorder yielded strikingly consistent findings in the United States and Europe. Clinical features, course, prognosis, and cognitive and neurobiologic correlates clearly distinguish this disorder from other psychiatric disorders in which depersonalization/derealization symptoms occur. Also, valid and reliable instruments exist for screening and diagnosis, such as the Cambridge Depersonalization/Derealization Scale developed by Mauricio Sierra and Germán Berrios (see section on Nosology and Table 20–2).

Etiology

Discrete Behavioral States Theory and Depersonalization/Derealization Disorder. Individuals with depersonalization/derealization disorder describe highly distressing, continuous or relapsing/remitting DBSs characterized by alienation from somatic, perceptual, cognitive, and affective processes. Unlike individuals with psychotic or delusional disorders, reality testing remains intact: for example, when queried these individuals acknowledge that they "feel" terrifyingly dead but they do not literally believe that they are dead. Individuals with the disorder usually have limited ability to modulate or moderate these states. Some describe states characterized by numbness and detachment. Typically, these individuals' emotionless, robotic outward presentation belies their substantial subjective distress at experiencing chronically anhedonic states of being. Conversely, many individuals with depersonalization/derealization disorder present with states of overt agitation and desperation about experiencing disconnection from themselves and/or the world.



Genetics
Childhood maltreatment
Adolescent transitions
Chronic depersonalization
Other severe life stressors
Chemical triggers
Severe episodes of mental illness

FIGURE 20–2. Schematic integration of proposed models to explain depersonalization disorder.

Several models have been proposed to explain this disorder. A schematic integration is presented in Figure 20–2.

Psychodynamic. Traditional psychodynamic formulations have viewed depersonalization/derealization as a disintegration of the ego or as an response in defense of the ego. These explanations stress the role of overwhelming painful experiences or conflictual impulses as triggering events. The high rates of depersonalization/derealization symptoms in normal adolescents and in patients conceptualized as having borderline or narcissistic personality organizations are cited as evidence that ego immaturity, ego deficits, and/or self-self-system lability and/or deficits predispose to these conditions. More recently, attention has been drawn to the similarities between depersonalization/derealization and obsessive-compulsive symptoms. Patients with depersonalization/derealization disorder often display obsessive-like behaviors with respect to their symptoms. The split between an observing and a participating self is likened to the division between intellect and emotion in obsessive patients. Both groups respond to serotonin reuptake inhibitors, although the therapeutic response for patients with depersonalization/derealization disorder is usually much less robust.

Traumatic Stress. As described in prior sections, acute peritraumatic depersonalization/derealization states are common in accident victims and military recruits undergoing high-stress training, permitting peritraumatic, survival-based downregulation of autonomic functions (e.g., heart rate, blood pressure, rate of respiration, and of the HPA axis). In depersonalization/derealization disorder these states can be conceptualized as disconnecting from their earlier survival function and becoming persistently autonomous, activated by later stressful and/or traumatic experiences (e.g., financial, social, medical, psychopharmacological, and/or other stresses).

Other antecedent experiences to the development of depersonalization/derealization disorder include the unexpected, sudden death of a family member or close friend; sexual orientation struggles in adolescence; and major family/work stresses. In some cases of severe and/or prolonged mood or anxiety disorders with comorbid DSM-5-diagnosed depersonalization/derealization disorder, this latter disorder becomes chronic after remission of the other disorders.

A controlled clinical study found significantly more childhood trauma, especially emotional abuse perpetrated by parents, in well-diagnosed patients with depersonalization/derealization disorder compared with healthy controls. Unlike the control group, separation or loss of parents appeared protective of development of depersonalization/derealization symptoms. Overall dissociation scores were related to sexual and emotional abuse in the control group, but emotional abuse alone predicted depersonalization/derealization scores.

In support of the power of emotional abuse as a traumatic stressor and of its link to dissociation, Martin H. Teicher and colleagues have shown that parental verbal/emotional abuse was “a potent form of maltreatment” in a community sample of 554 young adults. In this study, verbal/emotional abuse experiences resulted in moderate to large increases in measures of dissociation, anxiety, depression, anger-hostility, somatoform symptoms, and symptoms of “limbic irritability,” such as paroxysmal somatic disturbances, brief hallucinatory events, automatisms, and dissociative experiences.

In a recent report, a Puerto Rican convenience sample of 40 women with a history of interpersonal trauma was compared with 40 control women without such history. Subjects completed Spanish versions of the DES, a factor-analytic derived depersonalization/derealization subscale of the DES (DES-D), the CDS, the Patient Health Questionnaire (PHQ-9), and a validated measure of types and severity of prior physical, sexual, and/or emotional abuse. Half the trauma sample reported a history of sexual abuse. Participants reporting more frequent abuse experiences also had significantly higher mean depersonalization/derealization scores on the DES, DES-D, and CDS. The largest effect sizes were for CDS and depression scores. One-quarter of the trauma group scored above the CDs cutoff score of ≥70, indicating high likelihood of a depersonalization/derealization disorder diagnosis. As in other studies (see section on Epidemiology), there was a significant correlation between PHQ-9 depressive and depersonalization/derealization scores. The authors concluded that, despite limitations of this convenience-sample study, the findings provide evidence of a significant linkage between antecedent trauma and dissociative symptoms in a Latin American cultural context.

In a recent study of 106 women with PTSD (80% PTSD dissociative subtype) in a specialized partial hospital trauma program were studied using a multivariate linear regression model of multiple childhood adversities. These included physical abuse, emotional abuse, sexual abuse, emotional neglect, and physical neglect. In this sample, emotional abuse was significantly associated with higher depersonalization/derealization scores and physical abuse was associated with lower dissociation scores. There was no interactive effect of multiple types of abuse.

However, some studies have not shown significantly higher rates of childhood interpersonal trauma in individuals with depersonalization/derealization disorder compared to control groups (e.g., with depressive disorders). Some of these studies have found significantly higher rates of a first-degree relative with severe psychiatric illness (e.g., psychotic disorder or bipolar disorder). One hypothesis is that the chronic fear engendered by the relationship with the psychotic relative was etiologic in the development of the depersonalization/derealization disorder. For example, one patient reported that throughout her childhood her father and older brother left her to manage on her own her mother's psychotic and violent episodes. Despite intense terror and dread about her own safety, the patient feared more for her mother's safety. She followed her mother through the house while the mother typically brandished a large kitchen knife, loudly verbigerating at invisible persecutors.

As in the case of individuals with dissociative amnesia, an earlier history of trauma and/or severe stress may be present but is not the initiating factor in the onset of depersonalization/ derealization. Symptom exacerbations are commonly related to negative emotions, high levels of sensory input, and threatening, stressful, and/or unfamiliar situations. Traumatic or stressful events may precipitate or exacerbate depersonalization/derealization disorder symptoms.

Many individuals with depersonalization/derealization disorder do not identify an immediate traumatic antecedent and do not report a clear precipitant to disorder onset. On the other hand, nontraumatic stressors—such as severe interpersonal, financial, or occupational losses—have been associated with the onset or exacerbation of the disorder. Psychopharmacological stressors, most commonly marijuana and hallucinogens, can sometimes precipitate chronic depersonalization/derealization. These individuals can be conceptualized as having a neurobiologic or genetic vulnerability to chronic depersonalization/derealization after drug use, although early life trauma can also play a role.

Mr. A, a successful 42-year-old actor, was referred for psychiatric evaluation. Since his late teens, he had abused alcohol and a variety of drugs, usually in binges lasting several weeks. After one of his brothers died of a heroin overdose, he engaged in a several-week binge on alcohol, marijuana, and inhaled and smoked cocaine. At the conclusion of the binge, after his first sober night "crash," he awakened with intense, highly distressing depersonalization/derealization experiences. He reported feeling completely alien and disconnected from himself, his emotions, and his awareness of the environment. He reported estrangement from his body, not experiencing it as connected to him, feeling as if his limbs were either too far away from him or too close. He reported that the world seemed flat and unreal, almost as if it were a painting. He tried to read scripts that he had been given to prepare for auditions but the words seemed disconnected from him. When he tried reading scripts aloud, his voice sounded alien, "tinny," far away, and unfamiliar. He denied being fully out of his body, observing himself as if he were another person. However, he reported being "just beside myself, not really in myself, like to one side. It's terrible; I can't get back to me. I don't feel connected to who I am. I know I am feeling things, but I don't know what they are. All I feel is desperate to get back to how I used to be."

He described his father as a dictatorial alcoholic who berated him throughout his youth, calling him names, humiliating, and mocking him. He denied a history of childhood sexual abuse but said that both parents would hit him "randomly, with whatever they got their hands on." The father terrorized the family, including repeatedly insulting and hitting the patient's mother in front of the patient and his younger brother. Substance abuse began in adolescence to numb himself from feeling terrified, impotently enraged, and humiliated. He described substance abuse, depression, and suicide attempts in first-degree relatives, including his deceased brother, no family members had sought mental health treatment and it was stigmatized in his family. A complete physical, laboratory, and neurologic work-up were all were within normal limits. Due to the symptoms, he stopped using alcohol and drugs completely, literally becoming phobic of drug use. However, several years later, he remained chronically depersonalized and only able to work in a very limited way. He reported distress that he cannot experience emotions about his brother's death or the family violence and dysfunction that led both of them to abuse substances with such adverse outcomes. He had little response to trials of antidepressants, mood stabilizers, and naltrexone. He reported mild improvement in mood and ruminations about his symptoms on fluvoxamine 300 mg daily and naltrexone 100 mg daily. Primarily, he was managed in a supportive psychotherapy, having had limited response to trials of cognitive-behavioral, dialectical behavioral, and psychodynamic psychotherapy.

Cognitive Theories. In the last decade, increasing attention has been paid to cognitive and behavioral aspects of chronic depersonalization/derealization, essentially positing that an initial, relatively benign, and possibly transient dissociative response is reinforced, maintained, and exacerbated by a vicious cycle of dysfunctional cognitions and behaviors. E.C.M. Hunter and colleagues in the United Kingdom have put forth such a cognitive-behavioral model, proposing that an initial trigger (e.g., trauma, anxiety, depression, stress, fatigue, intoxication) can induce transient symptoms of depersonalization/derealization which are subsequently cognitively processed by an individual as either situational or catastrophic. If the attributions are situational, and therefore more benign, the depersonalization/derealization symptoms will tend to fade as the situational factors alleviate. However, if the attributions are catastrophic, they may evoke overwhelming fears such as going mad, losing control, becoming invisible, or having a permanent brain dysfunction. In turn, these fears may lead to increased anxiety coupled with paradoxically decreased arousal, resulting in increased intensity of the depersonalization/derealization symptoms as the individual enters the maintenance phase. During this phase, individuals may start to avoid situations that they associate with symptom provocation; become preoccupied with safety behaviors (such as acting “normal”); develop cognitive biases resulting in symptom over-monitoring; and experience a reduced threshold for the perception of threat. Over time, these maintenance factors are thought to perpetuate or exacerbate the symptoms.

Diagnosis and Clinical Features

In clinical samples, the disorder is equally common in men and women but is often missed. Under-diagnosis is facilitated by several aspects of the disorder. Patients experiencing depersonalization/derealization symptoms have difficulty putting their ineffable experiences into words and may have problems with alexithymia. They often fear that they may be seen as “crazy” if they **do** describe their symptoms and may be reluctant to speak about them. They may describe their severe suffering in ways that do not adequately convey their distress to an examiner; for example, repeatedly stating that, “I feel dead,” “Nothing seems real,” or “I’m standing outside of myself.” Individuals with depersonalization/derealization disorder typically endure an intensely unpleasant, and often disabling, subjective experience. Many say that they would gladly exchange the depersonalization/derealization for physical pain that would at least reconnect them with their body. Others say they do not contemplate dying because they already are dead. Some patients may appear remarkably detached and unemotional, due to profound dissociation of affects. As the patient’s complaints do not match their affective presentation, clinicians may not take the severity of this disorder as seriously as they should.

There are several distinct components to experiences of depersonalization and derealization. Individuals may be reluctant or have difficulty describing their symptoms, and clinicians should familiarize themselves with the range of depersonalization/derealization symptoms for direct inquiry. *Depersonalization* may include a sense of bodily changes, duality of self as observer and actor, being cut off from others, and being cut off from one's own emotions. These individuals may suffer from teleopsia (objects appear further away), pelopsia (objects appear nearer than they are), metamorphopsia, micropsia, and/or macropsia. They may experience their body changing in size and shape; disintegration of time sense with little ability to assess how recently or remotely events occurred; *déjà vu*, *déjà vécu*, and *jamais vu*; numbing of emotions and perceptions, including the inability to perceive hunger or thirst; and feeling robotic, detached, and/or without thoughts or feelings. The individual may report out-of-body experiences or, as in the case example above, a highly dysphoric feeling of partial disconnection from oneself. On the other hand, in *derealization,* the world appears strange, foreign, or dreamlike. Objects may appear as if viewed from a great distance and as if they were two-dimensional, without depth or substance, or as if observed through a fog, mist, or hazy, frosted glass. Sounds come from a distance, muffled and distorted. Objects feel strange to the touch. Colors dim and lose their vitality. The faces of others change, becoming unfamiliar and frightening.

Two factor analytic studies of core symptoms of the disorder found convergent results. There were five discrete symptom clusters: unreality of self, defined as feeling detached from one's physical body, mind, and thoughts; perceptual alterations, encompassing visual, tactile, and somatosensory distortions; emotional numbing, characterized by blunted affect, detachment from pain, and abulia; anomalous subjective recall, consisting of disrupted experiences of memory and time; and alienation from surroundings, comprising symptoms of derealization.

A latent profile analysis of 303 individuals (57.4% male) with depersonalization/ derealization disorder at a British clinic for the disorder were assessed with the DES, CDS, Beck Anxiety Inventory (BAI), and questionnaires for past medical and psychiatric history, symptoms of depersonalization and derealization, triggers of episodes, and other aspects of the disorder.

The latent profile analysis resulted in five subgroups: three varied on low, moderate, or high symptom severity across measures. Two other subgroups diverged on dissociative symptoms: a high DES dissociation group with amnesia, absorption, and depersonalization/derealization; and a high depersonalization/derealization group with higher CDS scores, but lower DES scores, particularly amnesia and absorption. The authors did not assess trauma history or conduct diagnostic assessments for other dissociative disorders (e.g., MID, SCID-D, MDI) or for comorbid diagnoses (e.g., SCID-5 to rule out schizophrenia). They suggested that the high-dissociation group may be better characterized by a diagnosis of dissociative identity disorder or of dissociative amnesia as conditions "comorbid" with depersonalization/derealization disorder. They speculated that the high-severity group may include subjects with schizophrenia. The elevated DES absorption factor in the high-dissociation group suggests the high hypnotizability found in dissociative identity disorder and dissociative amnesia. Preliminary studies of hypnotizability in depersonalization/derealization disorder do not show elevated hypnotic capacity on standardized measures. Also, in terms of DSM-5-TR diagnostic rules, diagnoses of dissociative identity disorder or schizophrenia would supersede that of depersonalization/derealization disorder (see below in section on Differential Diagnosis).

Cross-Cultural Aspects of Depersonalization/Derealization Disorder

In the 1990s, anthropologist Richard Castillo described a set of depersonalization/derealization symptoms derived from research in multi-cultural populations that was intended to broaden the cross-cultural validity of depersonalization/derealization disorder. Castillo's cluster of symptoms is similar to the more recent data-derived factor analytic models in Western samples, suggesting that the original "Western" descriptions may have been based on a limited sample of individuals. Components of Castillo's description that coincide with these contemporary descriptions include: persistent or recurrent experiences of depersonalization and/or derealization in which familiar experiences of the self and environment become distorted, potentially resulting in physical and emotional numbing; alterations in body image; experiences of being an outside observer of one's mental processes or body; feeling like an automaton; time disturbances; feeling as if one's body or environment is "unreal" or dreamlike; and visual distortions (e.g., macropsia).

Relevant to diagnosis, the depersonalization/derealization experience must not occur exclusively during a culturally approved religious, spiritual, or ritual activity (e.g., meditative practice) and is not considered normal by the cultural standards of the patient's own social group(s). However, some individuals may initially induce these experiences intentionally but over time lose control over them and develop fear and aversion for related practices.

Differential Diagnosis

The variety of conditions comorbid with depersonalization/derealization disorder complicates the differential diagnosis. These include major depressive disorder (73%); any anxiety disorder (64%); obsessive-compulsive disorder (21%); avoidant personality disorder (23%); and borderline personality disorder (21%). Symptoms of depersonalization/derealization may be associated with PTSD, ASD, bipolar disorder, schizophrenia, dissociative identity disorder, and dissociative amnesia, among others. Depersonalization/derealization symptoms may also result from a medical or neurologic condition, particularly seizure disorders, intoxication or withdrawal from illicit drugs, or as a side effect of medications (e.g., over-the-counter cold medications containing dextromethorphan; prescription or over-the-counter medications with anticholinergic potency). A thorough medical and neurologic assessment is not routinely needed, except for patients whose symptoms or course appear atypical, or if there is reasonable suspicion or evidence of medical or neurologic disorders or toxicity. Expert consensus suggests consideration of medical, neurological, and toxicologic evaluation when the depersonalization/derealization begins after age 40; there are focal neurologic findings; symptoms of numbness or tingling in extremities or sudden onset of symptoms of head pressure; history of head injury, seizure, or brain disorder; or infectious diseases or other medical conditions that can affect the CNS (e.g., systemic lupus, Lyme). Other medical conditions that can generate depersonalization/derealization include migraine, sleep apnea, vertigo, Ménière disease, metabolic diseases, and delirium. In general, depersonalization/derealization symptoms with medical etiology have a predominantly sensory character without the elaborated descriptions and personalized meanings common to psychiatric etiologies.

Work up should include standard laboratory tests, specialized labs (e.g., for autoimmune disorders), and urine and/or serum drug screens. Sleep-deprived EEG, and sometimes ambulatory or inpatient telemetric EEG, may be necessary to rule out focal seizures with impaired awareness (partial complex seizures). Brain imaging may be necessary to assess for structural abnormalities or other processes, as well as specialized assessments (e.g., vestibular testing, polysomnogram).

Drug-related depersonalization/derealization is typically transient, but persistent depersonalization/derealization may follow an episode of intoxication with a variety of substances, notably marijuana, hallucinogens, MDMA (Ecstasy), ketamine, and more recently salvia.[1] When depersonalization/derealization disorder is precipitated by drug use, there is no difference in the clinical course from depersonalization/derealization disorder without this precipitant.

To establish a differential diagnosis, a thorough and detailed psychiatric history needs to be obtained, especially in the presence of comorbid mood and anxiety disorders. Current diagnostic criteria require that the chronic depersonalization/derealization not occur exclusively in the presence of other disorders. It is common to obtain a history whereby an earlier and frightening episode of severe anxiety or depression—which conceivably may have acted as an internal stressor and destabilized a person’s sense of self—may precipitate chronic depersonalization/derealization. Subsequently, the latter continues even after the initial anxiety or mood episode remits. In another common scenario, depersonalization/derealization disorder tends to be more refractory, often continuous for periods of many years or decades, while the comorbid disorders go into periods of remission, whether with treatment or spontaneously. Conversely, patients who are severely and chronically ill with depersonalization/derealization disorder may become unremittingly depressed in response to their primary dissociative disorder, leading to misdiagnosis of a primary affective disorder. As discussed above, significant depersonalization/derealization symptoms may be found in dissociative identity disorder, often with CDS total scores several times higher than the cutoff score of ≥70 (e.g., 150 to 220) considered diagnostic for depersonalization/derealization disorder. Individuals with generalized dissociative amnesia, as well as patients with the childhood autobiographical memory deficits (CAMD)-form of dissociative amnesia, may experience depersonalization/derealization as a manifestation of the dissociative disorder and/or other comorbidities (e.g., PTSD, depression, obsessive-compulsive disorder, conversion disorder). from other dissociative disorders.

As a defining differential-diagnostic point to discriminate depersonalization/derealization disorder from psychotic disorder, patients with the former condition generally have intact reality testing about perceptual alterations. Also, the presence of a psychotic thought process, overvalued ideas, ideas of influence/reference, and Schneiderian symptoms distinguish depersonalization/derealization disorder from psychotic spectrum disorders such as schizophrenia, prodromal schizophrenia, or schizotypal personality disorder. The diagnosis of depersonalization/derealization disorder is based on the “as if” experiential nature of depersonalization/derealization, without distorted, delusional, dereistic cognitive explanations. This is similar to the assessment of a psychotic process accompanying obsessive-compulsive symptoms. A study comparing perceptual alterations and magical ideation in individuals with depersonalization/derealization disorder and healthy volunteers found that people with the disorder only had elevated perceptual, but not cognitive, distortions.

Course and Prognosis

Depersonalization or derealization symptoms after traumatic experiences or intoxications commonly remit spontaneously. Depersonalization/derealization accompanying mood, psychotic, or other anxiety disorders commonly remit only with definitive treatment of these conditions.

One-third of individuals with depersonalization/derealization disorder have an episodic, relapsing, and remitting course; one-third a chronic course; and one-third an episodic course that becomes chronic. Many patients with chronic depersonalization/derealization disorder are characterized by severe impairment in occupational, social, and personal functioning. In most studies, mean age of onset appears be in late adolescence or early adulthood. Most patients with depersonalization/derealization disorder are initially treated for the secondary anxiety and mood disorder symptoms. The primary nature of the depersonalization/derealization disorder is often only recognized later, if at all. These individuals, like those with dissociative identity disorder, may spend many unproductive years in the mental health system before receiving a correct diagnosis, “failing” to respond to standard treatments and often characterized as “treatment resistant.” As in the case of individuals with dissociative identity disorder, expert clinical opinion suggests that persons with untreated depersonalization/derealization disorder may, after years of unproductive treatment, suffer demoralization and clinical deterioration. This may lead to a chronic and disabling course with impairment in family, social, and occupational functioning.

Treatment

Clinicians working with patients with depersonalization/derealization report them to be singularly refractory to treatment. Several factors may lead to this perception. Due to the typically substantial delay in diagnosis of the condition, clinicians often do not have the opportunity to intervene until years after its onset, at which point the symptoms tend to become constant, nonfluctuating, and less responsive to therapeutic intervention. Clinical reports suggest that individuals with depersonalization/derealization disorder seen earlier during their disorder, and those who continue to have fluctuating or episodic symptoms over the years, may be more responsive to treatment.

Psychotherapy. Many studies describe a range of psychotherapies to treat depersonalization/derealization disorder, including psychodynamic, cognitive, cognitive-behavioral, hypnotherapeutic, and supportive therapies. No systematic data exist that compare these modalities. There are few systematic studies of psychotherapy for depersonalization/derealization disorder.

Psychodynamic treatment focuses on underlying threats to self-constancy that give rise to intolerable affective states. According to psychoanalytic theories, a person in whom the cohesiveness or stability of self-representations is profoundly threatened may resort to depersonalization/derealization (i.e., a disconnection from the self) as a solution. Similarly, psychodynamic theories suggest that depersonalization/derealization can be linked to various levels of personality organization. In individuals with a psychotic-spectrum disorder, depersonalization/derealization may be triggered by impaired self-other differentiation. In borderline psychopathology, unstable and shifting self-representations may be associated with depersonalization/derealization. In narcissistic pathology, when self-constancy is threatened by the real or imagined loss of self-objects serving purposes of object constancy, depersonalization/derealization may arise. Finally, in neurotic psychopathology, de-repressed self-representations associated with overwhelming intrapsychic conflict may trigger depersonalization/derealization. In psychodynamic psychotherapy, the therapist can observe and analyze, often in a moment-to-moment fashion, these and related dynamics as they occur during psychotherapy sessions and/or are described by the patient.

More recently, Daphne Simeon has proposed that addressing the fear of affects is a crucial component of psychotherapy for depersonalization/derealization disorder. Dissociation of affect (“not feeling”) and alexithymia (difficulty identifying and verbalizing internal emotional states) are core components of the condition. Depersonalized/derealized patients will frequently recount traumatic or stressful life experiences in a highly robotic, matter-of-fact, and emotionless way. The goal of an affect-based therapy is to uncover, experience, label, own, and verbalize intolerable emotions and to process these emotions in the context of underlying conflicts and disavowed self-representations and self-states. Eventually, such emotions can be gradually integrated with the core sense of self so that the individual can transition from an “unreal” self to a more “real” owned self. Which affects need to be dealt with vary greatly depending on each person’s history and sense of self, ranging from the negative to the positive, and can include anger, grief, sorrow, shame, guilt, excitement, and love. In a simplistic sense, this approach is “opposite” to the affect regulation component of the treatment of trauma-related conditions such as PTSD or dissociative identity disorder, as the goal in the therapy of individuals with depersonalization/derealization disorder is to activate and experience rather than to better modulate and regulate intense affects. On the other hand, as noted in the section on dissociative identity disorder, patients with dissociative identity disorder and the dissociative subtype of PTSD may attempt to mobilize depersonalization/derealization, affect suppression, and state shifting to distance and modulate posttraumatic intrusions. Frequently, in patients with this PTSD subtype, this effort at dissociative distancing fails and patients experience severe flashbacks. They may report, and/or display, oscillations between being all “shut down” and experiencing overwhelming flashbacks that can completely overwhelm awareness of current reality when they do break through into consciousness.

In recent years, a disorder-specific cognitive-behavioral therapy approach to depersonalization/derealization disorder has been developed and tested, based on the cognitive-behavioral model outlined earlier. In this type of treatment, the focus is on developing techniques to cognitively reinterpret symptoms as less threatening; to reduce symptom monitoring; and to diminish avoidance and safety behaviors. In an uncontrolled, prospective treatment trial of 21 patients utilizing this approach, significant reductions in ratings of depersonalization/derealization, depression, and anxiety were found. In addition, by the end of the 12-week treatment, 29% of participants no longer met diagnostic criteria for the disorder. Recently, a small, uncontrolled study of a staged psychoeducational, mindfulness, and CBT group therapy intervention for adolescents with depersonalization/derealization disorder found that, at 6 months follow-up, about two-thirds of the patients decreased CDS scores below cutoff criteria.

A proportion of severely impaired patients with depersonalization/derealization disorder may require long-term supportive treatment. The clinician will need to be acutely aware of the patient's interpersonal sensitivity, distress, and sense of hopelessness about the condition. Some supportive psychotherapy elements are very important for the effective treatment of all patients with the disorder. These include psychoeducation, such as giving the condition a name and reassuring the patient that it will not evolve into a psychotic disorder and that there is no evidence of permanent brain damage. Also, psychoeducation and supportive interventions can help the patient lift the barrier of secrecy based on shame about symptoms in general, alleviate guilt or shame associated with a drug-induced onset, and provide hope for the future. In this educational/supportive/cognitive-behavioral model, the clinician challenges the patient's experience of the "physicality" of the experience. This can include emphasizing that depersonalization/derealization disorder is a psychological disorder, as physical as it may feel; providing a sense of control over the symptoms that may be perceived as continuous in intensity; using techniques that can help modulate the level of arousal and indirectly soften the symptoms; and reassuring women who are considering pregnancy that the heritability, as far as it is known, appears to be limited. There are no adequate data on the utility of either hypnosis or EMDR in treating chronic depersonalization/derealization. One study found that these patients had relatively low hypnotic capacity on standardized hypnotizability measures, suggesting that this may not be a helpful intervention for patients with depersonalization/derealization disorder.

Pharmacotherapy. Extensive retrospective treatment histories have not provided support for major symptom improvement with any of the known and widely used classes of psychiatric medications, although benzodiazepines, serotonin reuptake inhibitors, and stimulants appear to be partially efficacious for some patients. In past decades typical antipsychotics were widely used for chronic depersonalization/derealization, often as first-line treatment, as many clinicians viewed depersonalization/derealization symptoms as indicative of a psychotic-spectrum condition. There is no empirical evidence for the efficacy of typical or atypical antipsychotic medications in depersonalization/derealization disorder. They should only be used to target overwhelming anxiety or mood disturbance associated with the depersonalization/derealization. Common side effects of these medications may *exacerbate* an experience of emotional deadness and lack of emotional response to oneself or the world. Thus, in some individuals with depersonalization/derealization disorder these medications may *increase* the target symptoms. Typically, the numbing/deadening neuroleptic side effects set in gradually as dosage increases. Thus, neither patient nor clinician appreciates the source of symptoms worsening—sometimes leading to even higher neuroleptic dosage.

There is some anecdotal support for the use of serotonergic antidepressants (e.g., SSRIs, clomipramine [Anafranil]) in depersonalization/derealization disorder. However, a recent large randomized, controlled trial of fluoxetine found only a statistically marginal, and clinically minimal, improvement in depersonalization/derealization compared to placebo. Depersonalization/derealization and dissociation scores did not significantly decline in the fluoxetine-treated group, paralleling patients' subjective reports that their symptoms had not changed. On the other hand, patients reported feeling somewhat better and less distressed by the symptoms. Within the fluoxetine-treated group, depersonalization/derealization responders were more likely than nonresponders to show improvement in comorbid anxiety disorder symptoms. This may account for the experience of being less distressed by their symptoms, although the depersonalization/derealization symptoms remained unchanged.

Therefore, it appears that serotonergic antidepressants are unlikely to be of major benefit for depersonalization/derealization symptoms but may potentially ameliorate comorbid obsessive-compulsive, depressive, and/or anxiety symptoms. Lamotrigine—a mood-stabilizing anticonvulsant that promotes glutamate release—initially showed promise for depersonalization/derealization disorder symptoms in a small open-label study. However, a subsequent small crossover placebo-controlled trial found that all nine participants were nonresponders. Some have suggested that the combination of SRIs and lamotrigine may have additive benefit in treating the disorder, but no empirical support exists for this hypothesis.

Opioid antagonists such as naltrexone (Revia), cognitive enhancers, benzodiazepines, and stimulants all have had some benefit in clinical treatment of specific patients with depersonalization/derealization disorder. In uncontrolled and/or proof-of-concept studies, a trial of repetitive transcranial magnetic stimulation (rTMS) for depersonalization/derealization disorder has shown efficacy in some patients. rTMS models have involved stimulation of the TPJ, and the VLPFC, areas that have been implicated in the generation of depersonalization/derealization disorder symptoms.

DEPERSONALIZATION/DEREALIZATION DISORDER (DDPD) CASE 2

Ms. R a 27-year-old unmarried graduate student with a master's degree in biology came to clinical attention for intermittent episodes of "standing back," usually associated with anxiety-provoking social situations. When asked about a recent episode, she described presenting a paper in a seminar course. "All of a sudden, I was talking, but it didn't feel like it was me talking. It was very disconcerting. I had this feeling, 'Who's doing the talking?' I felt like I was just watching. Watching someone else talk. Listening to words come out of my mouth, but I wasn't saying them. It wasn't me. It went on for a while. I was calm, even sort of peaceful. It was as if I was very far away. In the back of the room somewhere—just watching myself. But the person talking didn't even seem like me really. It was like I was watching someone else." The feeling lasted the rest of that day and persisted into the next as it gradually dissipated.

She thought that she remembered having similar experiences during high school but was certain that they occurred at least once a year during college and graduate school. Although she said that she usually felt detached and sometimes peaceful during the experience, she was upset at the thought that she would likely have more episodes. She complained that the sudden onset, the eeriness of seemingly watching an almost unrecognizable version of herself from a distance, and the sense of not "being in the world" were almost unbearable in retrospect.

Ms. R, an only child, reported recurrent, intense childhood fear and distress when overhearing or witnessing the frequent violent arguments and periodic physical fights between her parents. She remembered lying awake in bed, listening to them, imagining the terrible things that were occurring, or about to occur, between them. In addition, the family was subject to many unpredictable dislocations and moves owing to the patient's father's intermittent difficulties with finances and employment. The patient's anxieties did not abate when the parents divorced when she was a late adolescent. Her father moved away and had little further contact with her. Her relationship with her mother became increasingly angry, critical, and contentious. She was unsure whether she experienced depersonalization during childhood while listening to her parents' fights.

After receiving a depersonalization/derealization disorder diagnosis, she began a multimodal treatment to address symptoms. She became aware of more chronic depersonalization/derealization symptoms with detachment from her emotions, distorted experiences of her body, metamorphopsia, and feeling that she was permanently separated from other people, as if behind a glass wall. She found psychoeducation about her symptoms relieving, as she had a name and concepts to explain her experiences not, as she put it, "just plain crazy." Also, she was helped to look at the impact the family violence and dislocations had on her development. She recalled ongoing terror that her parents would move and that she would be left behind, although at other times she guiltily fantasized about, after abandonment, being adopted by a "nice" family. She changed schools often and felt "different" from other children, fearful to not invite anyone to her house as she could not predict what her parents would do.

She found ongoing psychoeducation validating, allowing her more freedom to look at the chronic terror that characterized her childhood. She realized the extent of emotional neglect she experienced, along with witnessing the family violence. She responded as well to psychodynamically informed interventions that helped her notice increasing depersonalization/derealization in the moment, particularly at times of impending strong emotions like fear, anger, and shame. Cognitive interventions helped her become aware of many distorted beliefs that she harbored, feeling responsible for her parents' well-being, blaming herself for her difficulties in development, as well as associated symptoms of depression. On diagnostic exploration, she described a variety of obsessive-compulsive symptoms since childhood, including magical thinking that they would protect her from the chronic danger she experienced at home. She had a partial response to fluvoxamine 200 mg daily with decreases in panic, obsession-compulsive, and depressive symptoms. As treatment progressed, she was amazed at how strangely good it felt to be aware of her emotions, perceptions, body, and mind, as well as experiencing joy when engaged in music and art and when hiking in the countryside. She began to develop a group of friends and became involved with her first boyfriend. She was amazed at how accepting they all were of her and that they too had issues with dysfunction they experienced in their families of origin.

OTHER SPECIFIED DISSOCIATIVE DISORDERS

The category *other specified dissociative disorders* describes conditions characterized by a primary dissociative response that do not meet diagnostic criteria for one of the DSM-5-TR dissociative disorders. This category encompasses a clinically heterogeneous group of dissociative conditions, often with multiple comorbidities, and provides a diagnostic home for several Western and non-Western idioms of distress. Many patients with these conditions have a current or past history of severe trauma. To receive a diagnosis of other specified dissociative disorder, the dissociative presentation must not be better accounted for by ASD, PTSD, specific dissociative disorders, or another disorder.

The other specified dissociative disorder diagnosis in DSM-5-TR lists four examples to assist clinicians in recognizing conditions encompassed by this category. Research findings may support the future inclusion of some or all these as specified dissociative disorders and/or lead to modifications of the diagnostic criteria for the current DSM-5-TR dissociative disorders. Future studies should obtain additional data on each example to determine whether it represents a stable disorder with a typical set of symptoms as well as on its etiology, precipitants, neurobiology, course, treatment response, and other outcomes. Some patients who initially receive this diagnosis will ultimately be better conceptualized as having another dissociative disorder, such as dissociative identity disorder.

EXAMPLE 1: ATYPICAL PRESENTATIONS NOT MEETING FULL DIAGNOSTIC CRITERIA FOR DISSOCIATIVE IDENTITY DISORDER

Definition

Example 1 of other specified dissociative disorder covers presentations similar to dissociative identity disorder but with: (a) less-than-marked discontinuities of self and agency and/or (b) alterations of identity or episodes of pathologic possession in an individual who reports no dissociative amnesia. This is an analog of the ICD-11 partial dissociative identity disorder diagnosis.

Diagnosis and Clinical Features

As noted in prior sections, a major goal of the DSM-5-TR Work Group was to reduce the frequency of DSM-IV-TR dissociative disorder NOS diagnoses. Nonetheless, Example 1 is meant to indicate cases where the experience of self-states is not sufficiently distinct and/or the discontinuities of self insufficiently apparent or severe to warrant a diagnosis of dissociative identity disorder (see section on Changes in Diagnostic Criteria to the Dissociative Disorders).

Example 1 can be used as an initial placeholder for a putative diagnosis of dissociative identity disorder. This allows additional history-taking, clinical observation, use of diagnostic screening inventories and interviews, and acquisition of data from collateral informants. Over time, with further assessment, most individuals with this diagnosis will likely meet criteria for dissociative identity disorder. Rarely, clinicians describe patients who fulfill the DSM-5-TR Criterion A for dissociative identity disorder, but in whom dissociative amnesia is not reported or observed, even on careful questioning. Clinical experience suggests that, with careful sequential observation, most of these individuals ultimately meet the amnesia criterion for dissociative identity disorder. Ultimately, the clinician usually: (a) detects subtle dissociative amnesia symptoms; (b) realizes that the patient manifests dissociative amnesia for episodes of dissociative amnesia; (c) witnesses the patient not recalling several minutes of a therapy session, with the patient unaware that this has occurred); and/or (d) discovers subtle dissociative amnesia for aspects of the life history but virtually no contemporary dissociative amnesia symptoms such as ongoing blackouts, fugues, and unexplained belongings. Some of these patients may report continuity of memory inconsistent with dissociative amnesia. However, on careful evaluation, they report that they experience substantial parts of their autobiographical memory as depersonalized and derealized, without an affective, first-hand component: as if it happened to someone else, they heard about it, read about it, and/or have been told by friends and families about past events. Ultimately, the clinician and patient may realize that depersonalized/ derealized memory conceals typical forms of dissociative amnesia. These patients may be quite distressed, shocked, ashamed, and scared to acknowledge an extensive autobiographical memory deficit. They can go into a crisis when they realize that they may not be able to count on their memory to recall what happened during important parts of their lives.

Some patients with dissociative identity disorder who have achieved partial, but not complete, unification of self-states may continue to display these states, albeit usually in much more attenuated form, and may have significantly improved memory continuity. As treatment progresses, they may no longer meet Criterion A for dissociative identity disorder. Patients with dissociative identity disorder who achieve complete unification do not manifest self-states or dissociative amnesia. Under significant stress or with later life trauma, however, some of these individuals may display reactivated self-states but usually without the distinctness that manifested during earlier phases of treatment. Also, they may report dissociative amnesia symptoms for the stressful events that led to the disruption in unification. Technically, some of these patients meet diagnostic criteria for other specified dissociative disorder. As noted in the section on etiology, there are no studies that examine the question of change in taxon membership when individuals with dissociative identity disorder achieve stable unification.

Treatment

Based on research on the DSM-IV-TR category of dissociative disorder NOS, most patients with Example 1 of other specified dissociative disorder will require a treatment approach similar to the one recommended for dissociative identity disorder.

COERCIVE PERSUASION

Definition, Diagnosis, and Clinical Features

The concept of *brainwashing* or *thought reform* emerged from Western reactions to the Soviet show trials of the late 1940s and alarm over Communist Chinese methods of coercive political re-education. These fears intensified during the Korean conflict after many American prisoners of war made anti-American statements. In 1950, a journalist, Edward Hunter (later identified as a Central Intelligence Agency [CIA] operative) proposed that the Chinese Communists had discovered techniques to modify mental attitudes and beliefs, a process that he called *brainwashing.*

After the Korean conflict Armistice, a team of psychiatrists and psychologists, including Robert J. Lifton and Edgar Schein, interviewed the returning prisoners. Similar CIA studies obtained information from Communist interrogators and former Soviet and Chinese prisoners. These studies concluded that the apparent brainwashing of these prisoners, as well as of the victims of the Russian show trials, was the result of police interrogation techniques including torture and severe physical and psychological deprivation. Cooperation by the prisoners was rewarded with the possibility of ending or pausing the torture or the provision of food and warm clothing. The reports concluded that the basic attitudes of the American prisoners in Korea had not been altered.

Subsequent investigations with other Korean conflict prisoners suggested that some of these individuals may have actually been subject to “thought reform” procedures that resulted in their continuing to falsely insist that they were spies. Studies by Schein and others concluded that changes in an individual’s basic beliefs could occur with torture, particularly when fostering prisoners’ dependency on the captors. The captors/torturers became the prisoner’s only human contact and used this form of coercion to control the prisoners’ behavior and sometimes their attitudes and views. Judith Herman, in her classic books on trauma, noted the similarity of the captor/captive relationship across various traumatic contexts: intra-familial child abuse, intimate partner violence, trafficking, and political torture.

The CIA and “Mind Control”. In the 1970s, the legacy of the fear of Cold-War-era “brainwashing” was revealed in declassified government documents and during Congressional hearings, which documented misuses of behavioral science by the CIA and other U.S. government agencies since the late 1940s. These efforts attempted to develop methods of behavioral control to combat and/or preempt potential Communist mind control “weapons.” The CIA studied or supported experiments in the United States and Canada on volunteers as well as unwitting or coerced subjects, including prisoners, psychiatric patients, and/or military personnel. These included the use of psychedelic drugs, marijuana, other toxins and intoxicants, radiation, hypnosis, sensory deprivation/overstimulation, repeated ECT treatments, and/or bizarre conditioning experiments. At least one individual killed himself during an LSD experiment. In the 1980s, a few older adults, permanently psychiatrically damaged U.S. and Canadian victims of CIA-funded “psychiatric” experiments during the 1960s reached a small monetary settlement with the U.S. and Canadian governments—neither of which admitted responsibility. Also, in anticipation of the congressional inquiries, the CIA leadership mandated destruction of most documents related to these “programs.”

According to reviews of remaining CIA documents, some CIA officials apparently believed that hypnosis could be used to create assassins or spies with hypnotically induced dissociated identity states and/or amnesia who could resist interrogation and torture. Other CIA officials doubted that this could be done successfully. However, due to the destruction of documents, it is unclear if the CIA ever undertook these “multiple personality” experiments. Popularized accounts continue to suggest that the U.S. government did attempt to do so. However, a careful reading of these cases shows that, based on available information, these individuals’ symptoms had little similarity to those of dissociative identity disorder.

“Cult” Mind Control

Allegations of brainwashing or mind control resurfaced in the late 1960s and 1970s in the context of some counterculture religious, self-help/psychotherapy, and political groups. The complex topic of what constitutes a “cult” spans the fields of psychiatry, psychology, sociology, anthropology, religious studies, and political science. The modern use of the term “cult” is usually pejorative, denoting a subset of “unconventional” people within religious or secular groups who hold views characterized as “extremist and/or false” and who often live under the control of a charismatic, authoritarian leader. However, the religious history of the United States is characterized by myriad religious sects and/or spinoffs from traditional religions; political movements; and schools of psychotherapy/self-help/self-improvement, among others. Some have quipped that a cult designation simply means, “A religion I don’t like.” Psychiatrist Marc Galanter reframed the religious cult mind-control debate by advocating the more neutral term *charismatic religious sects*, pointing out that some individual’s behavior within such a social group may reflect psychological adaptation rather than psychopathology.

“Destructive” cults are defined more precisely, although in multiple ways. These definitions tend to include a rigid authoritarian, hierarchical structure; violence toward members/outsiders, including rape/sexual torture of children and/or adults; abusive psychological/emotional control tactics; extreme isolation; confinement abuse; physical assaults; forced suicide and/or murder; violent psychological/ physical/ homicidal retaliation against those who challenge the group from within and/or try to leave; retaliation against outside critics of the group; and a financial structure that primarily benefits the leader(s). These cults may center on religion/ spirituality/ mysticism, politics, psychotherapy/self-improvement, and economic promise, among others.

Dissociation and “Mind Control”

In February 1974, the heiress Patty Hearst was reportedly kidnapped, tortured, sexually abused, and held in prolonged solitary confinement by a radical “cult-like” group, the Symbionese Liberation Army. After months of this treatment, Hearst was said to have been transformed into a new dissociative self/identity state, that of the revolutionary “Tania,” who aided her captors in criminal acts, including bank robbery and murder. A group of defense psychiatric experts including Louis J. West, Lifton, Martin Orne, and Margaret T. Singer advanced the theory that the Tania state was developed in response to torture and mind control. In this view, Hearst was under duress for violent behavior in the Tania state and thus not criminally responsible. They cited the “Stockholm syndrome,” based on a bank robbery and hostage situation in Sweden in which hostages reportedly “traumatically bonded” with the robbers, complicating the hostage negotiations. The Patty Hearst jury was not convinced and convicted Hearst.

Recent meta-analyses and case studies (e.g., that of Jaycee Dugard who was kidnapped and lived with her captors over 18 years, bearing two children) have raised questions whether Stockholm syndrome has reliable/valid diagnostic/syndromal criteria, and is more than an unscientific media construction. Dugard and other survivors of long-term kidnapping have denied having Stockholm syndrome, stating that they were not subject to “traumatic bonding,” but were doing their best to survive under the control of dangerous, homicidal individuals who avoided law enforcement on multiple occasions. Feminist critics have posited that Stockholm syndrome is better conceptualized as a patriarchal theory allowing male law enforcement to rationalize their failures in difficult hostage situations by blaming suggestible, psychologically “weak” women.

Dissociative “Ego States” and Cults

Some researchers on destructive cults posit that cult membership produces an “ego state” or dissociated self-aspect that allows the person to function ego-syntonically within the cult milieu.[2] This entity is not conceptualized as meeting criteria for a dissociative identity disorder self-state but suggests a diagnosis that may be analogous to Example 1 in this section. Some forensic experts in cases of violent behavior by cult members have posited that the influence of the cult leader results in a “shared psychotic disorder” (now Example 4 in Other Specified Schizophrenia Spectrum and Other Psychotic Disorder). Other experts disagree. No research studies have examined either question.

In this regard, some have pointed out that destructive cult groups like the People’s Temple, Hare Krishna, and Scientology seek out people who are psychologically vulnerable and seeking “meaning” in life, typically feeling estranged from religion, families, and communities. It has been hypothesized that cult members, as in pedophilia and intimate partner violence, initially “love-bomb” (groom) the vulnerable person, who then gradually is psychologically enmeshed in the group and manipulated into feeling responsible and obligated to it. Ultimately, the entire life of the person and all their main relationships—friendships, marriage, child-rearing—may be centered on the group. In the authors’ experience, destructive cult groups value highly dissociative individuals. The latter can readily enter deep trance states, block out pain, appear to have uncanny telepathic states, and manifest transformational, possession, and/or seemingly lycanthropic states.

Individuals leaving these groups, as those involved in destructive religious-offshoot cults like the polygamous Fundamentalist Church of Latter-Day Saints, may feel completely anomic, adrift, and alone in the “regular” world, shunned by their family and community, now living in a culture with which they have little experience. Some are subject to direct retaliation from group members after attempts to leave. Although this has not been studied, symptoms of depersonalization/derealization and possibly identity alteration could accompany individuals in these situations.

Dissociation and Identity Alteration in Children Associated with Armed Groups. Systematic torture and psychological coercion leading to self/identity alteration may have an even greater effect in children and adolescents. It is estimated that at least 300,000 individuals under 18 in over 30 conflicts worldwide take part in combat or act in support of armed groups as spies, cooks, laborers, sex slaves, and other functions. Authorities view the commonly used term “child soldier” as problematic, preferring “children associated with armed groups.” Like the terms “child prostitution” and “child pornography,” “child soldier” implies agency by the child. Authorities on child trafficking suggest eliminating the former terms and substituting more accurate ones such as, for example, “children sold for rape by and to adults in person, on video, livestreaming.” Some children join armed groups without gross coercion (e.g., for security; training; joining a liberation struggle; health care; escape from abusive families; deaths of family during conflict; destruction of home community; lack of opportunities for education or employment). Also, in some cultural settings, the term “underage soldier” is culturally comprehensible, but not “child soldier.” Here, adulthood begins at ages 12 to 14 after completion of specific ritual actions by the individual and/or community-specific rituals of transition into adulthood.

Based on studies of individuals who have left them, some of the most destructive groups only abduct children and adolescents and use systematic techniques to attempt to create new self/identity-states, loyally bonded to the group. The Lord’s Resistance Army (LRA) began in the late 1980s in Northern Uganda as a rebel movement. The LRA has since spread into the Democratic Republic of Congo, South Sudan, and the Central Africa Republic. As of 2008, this group had abducted over 20,000 children and, through extreme, murderous violence, displaced over 1.9 million people in Northern Uganda. Qualitative studies describe a series of systematic techniques used by LRA to sever attachments and bonds to children's families and cultural backgrounds, and to create a bond to the LRA group. The latter is to ensure loyalty as the group spreads beyond Uganda, especially into new cultural areas with different languages.

Techniques included isolation from others with shared cultural or linguistic characteristics, forced silence, and violent responses if individuals broke these rules or failed to learn the ethnic language of the group leaders. Children caught leaving the group often were publicly beaten to death by other children from their own ethnic group. Children were segregated by gender roles; girls were assigned to families to become servants or one of the wives of a group leader. Boys would be assigned to families of LRA leaders and given increasingly difficult tasks and loyalty tests to earn the right to carry a gun and become a soldier. Ultimately, ritual witchcraft ("*gris gris*") was performed on the boys as a rite of transition to becoming a soldier. Other forms of violence to sever old community ties involved raiding a child's home village and forcing him to kill members of his own tribe or family.

Case studies of adolescents and young adults who left the LRA and similar groups describe dissociative self-states with switching between violent group–oriented states and pacific self-states that want to reintegrate with their communities. Other survivors of these groups are described as strongly identified with the group values, dominated by violent self/identity-states for whom killing is a syntonic, desirable, almost a peak experience. A case study from the Netherlands describes a 24-year-old man from Sierra Leone, abducted at age 8 by a violent group like the LRA. He had witnessed, and was subjected to, violent and murderous atrocities as well as being forced to participate in them. Escaping at age 13, he eventually found asylum in the Netherlands. At the time of treatment, he met DSM-IV-TR diagnostic criteria for dissociative identity disorder, PTSD, and major depressive disorder. He switched among self-states, including malevolent, violent, group-affiliated self-states. He responded to a transference-focused, trauma/dissociation-focused psychotherapy that tracked self-state alterations and reframed the violent self-states as protectors.

Diagnosis and Clinical Features

As described above, there are a variety of situations where torture and psychological coercion are brought to bear on children, adolescents, and adults. It is possible that some, but not all, individuals subjected to extreme torture and psychological coercion develop dissociative symptoms such as depersonalization/derealization, dissociative amnesia, dissociative identity disorder, or self-states consistent with a diagnosis of Example 1 in this section. They may exhibit reduced cognitive flexibility, behavioral regression, and profound changes in values, attitudes, beliefs, and sense of self.

Treatment

There are no empirical treatment studies of individuals subjected to extreme coercion with indoctrination into a belief system that alters their identity. The triphasic trauma/dissociation treatment structure described in other sections would be a logical treatment framework. It is beyond the scope of this chapter to describe the sequential psychosocial interventions for disarmament, demobilization, and reintegration of children associated with armed groups. Some youth have been treated with a group therapy model to help build skills, process trauma, and rejoin their communities, if possible. Clinical case series and studies of children returning from these groups suggest that cultural competence is essential for successful treatment. Local categories of distress—in addition to or instead of DSM-5-TR PTSD, mood or dissociative symptoms—emphasize survivors being haunted nightly by the ghost of someone they killed, with hallucinations of the deceased. A systematic study of spirit possession in Northern Uganda found that *cen*, a specific form of possession by the spirit of a murdered person, was associated with the highest rates of prior witnessing, experiencing, and/or perpetrating extreme violence in former child members of LRA. The authors conceptualized this form of pathologic possession as a dissociative disorder, also associated with the highest rates of PTSD and depression. Fear of the *cen* was not only focused on the former soldier but on the expectation that the *cen* would afflict the youth's family or village if they returned without being healed.

In some cases, successful treatment consisted of specific healing rituals to expunge the possessing entity and to focus the sufferer on the future. In other reports, former soldiers have gone directly to ask for forgiveness from family members of those they have killed to permit reintegration into their community. These communities had procedures to structure asking for forgiveness, granting it, making amends, and reintegrating the former combatant back into their community.

ACUTE DISSOCIATIVE REACTIONS TO STRESSFUL EVENTS

Definition

Example 3 of other specified dissociative disorder describes acute, transient dissociative symptoms that last 1 month or less, and frequently only hours or days, and occur in reaction to stressful events. Because many of the briefer episodes ended when the patient was brought rapidly for emergency treatment, they might have lasted longer without intervention. Acute dissociative reactions cover a spectrum of severity, ranging from milder presentations of mixed dissociative symptoms to more severe but transient presentations that combine dissociative and psychotic symptoms. The prominence of somatic presentations of dissociation (e.g., conversion symptoms such as analgesia or paralysis) and psychological presentations (e.g., derealization, constriction of consciousness) also varies; a mix of both presentations is typical.

The acute dissociative symptoms may be precipitated by traumatic or nontraumatic stressors and persist for up to a few weeks after the stressor dissipates. Although patients are not always able to identify and report a stressful event as a potential cause of their disorder, a triggering event is usually recognized as precipitating the dissociative reaction once collateral information is obtained. The severity of the stressor varies, including frankly traumatic events such as the unexpected, violent death of a relative or experiencing a natural disaster. However, less stressful events, such as the loss of a significant relationship, may also precipitate this presentation. Community-level stressors, such as high levels of neighborhood violence, may predispose individuals to experiencing Example 3 reactions. The Western research literature has tended to subsume immediate dissociative reactions to stress or trauma into the concept of peritraumatic dissociation, defined as dissociative reactions occurring during and after a traumatic event. However, Example 3 does not require the presence of traumatic exposure, which distinguishes this condition from ASD.

Some cultural syndromes and other folk illnesses may fulfill criteria for Example 3 when they are characterized by acute reactions to adversity with mixed but transient dissociative symptoms. For instance, some cases of *ataques de nervios* (“attacks of nerves”) in Latino populations would best be described using this diagnosis. However, cultural concepts of distress do not have a one-to-one relationship with psychiatric disorders; instead, they cut across diagnostic clusters and must be translated into psychiatric categories at the level of the individual. For example, some persons with *ataques de nervios* qualify for a dissociative diagnosis—including other specified dissociative disorder—whereas others do not, meeting criteria instead for panic disorder, PTSD, or no psychiatric disorder.

Diagnosis and Clinical Features

The literature identifies several overlapping symptom clusters characteristic of these acute, brief, reactive dissociative conditions.

DSM-5-TR describes symptoms of constricted consciousness, depersonalization/derealization, perceptual disturbances (such as time slowing, metamorphopsia, brief amnestic experiences, transient stupor, and/or functional neurologic (conversion) sensory–motor deficits. Uncomplicated cases of Example 3 generate disturbances in interpersonal relationships and work-related functioning that usually resolve within a few days. Nevertheless, crisis intervention during the acute episode is often required. This category is also associated with a risk of suicidal behavior.

Acute dissociative reactions may be codified culturally into stereotyped reactions with associated causal attributions, courses, and treatment responses. In Latino communities, for example, cases of *ataque de nervios* may present with prominent dissociative symptoms consistent with Example 3 of other specified dissociative disorder. Reports of this cultural syndrome are frequent in U.S. Latino communities, ranging from 5 % to 11% across Latino subgroups in a representative community-based sample. Patients with *ataques* describe acute fits of emotionality associated with a sense of loss of control, usually precipitated by family stressors. Severity of *ataques,* assessed as lifetime number of episodes, is positively and independently related to self-reported dissociative symptoms measured with the DES and to clinician-diagnosed dissociative disorders, assessed with the SCID-D-R. In a representative community-based sample of U.S. Latinos, as well as in an urban primary care Latino sample, endorsement of *ataque* on a standardized survey was associated with a higher risk of suicidal ideation and behavior as well has higher morbidity (e.g., greater impairment).

Ms. C, a 27-year-old woman who migrated to the United States at age 14 from the Dominican Republic, had an episode of acute dissociative and aggressive symptoms while living in her brother's apartment in a large urban center. She had lost her apartment 3 months before, after separating abruptly from her common-law husband, and had been taken in by her brother into his rented apartment, along with her 7-year-old daughter. The morning of her acute episode, her brother informed Ms. C that she could not stay in the apartment any longer because he was being threatened with legal action for violating his lease by taking in additional family members.

After receiving the news, Ms. C reacted initially with apparent calm. However, during a discussion with her brother 2 hours later —when he again raised the topic of her departure and inquired as to her timeline for leaving—she became agitated, started screaming and crying, and attacked her brother with her hands and nails, aiming for his face. The brother was able to restrain her, but she ripped part of his T-shirt off his chest. For approximately one minute, whimpering softly, Ms. C slowly and repeatedly tore into small pieces the section of the T-shirt.

The episode waned gradually, and Ms. C became coherent again and asked her brother, "Why are you holding me like this?" Helped to lie down on a bed, she denied any memory of the event, recalling only the initial part of the argument. She did recall "an enormous rage" as her episode began and seeing her brother as "unreal" and "very small and far away" and she herself as "immensely powerful and tall, my head nearly touching the ceiling." She felt she was moving "in slow motion" at first but reported the absence of recall from that point forward.

Ms. C did not want to seek help for this episode—which she labeled an "*ataque de nervios*" (attack of nerves)—attributing the onset of her acute symptoms of depersonalization, derealization, time slowing, micropsia/macropsia, and micro-amnesia to the impact of the sudden news of her "eviction" by her brother. She felt this was a "normal" reaction, proportionate to the stressfulness of the situation, and would resolve on its own. However, Ms. C's family was very concerned about her amnesia, questioning her ability to care for her daughter on her own.

Later that afternoon, Ms. C's relatives escorted her to the psychiatric Emergency Room. She described feeling exhausted after her acute episode and was irritable during the interview, especially about her family's bringing her to the hospital. She slept on her gurney during most of the next 14 hours. The next day in the ER, Ms. C had two more episodes of sudden agitation, crying, and screaming, during which she attempted to scratch her face and leave the room. Because she responded quickly to verbal intervention and reassuring physical contact, she was not given medications or placed in restraints but was kept on one-to-one observation. Laboratory test results were unremarkable, as were an electroencephalogram and a lumbar puncture. On examination, she was crying softly, her mood was sad, and she reported transient depersonalization and derealization and ongoing amnesia for her acute episode. She was oriented to time, person, and place; had no psychotic symptoms; and denied current suicidal ideation.

Considering her gradual improvement and lack of evidence of immediate danger to self or others, the ER staff did not feel Ms. C qualified for an involuntary hospitalization, and she refused a voluntary admission. After 36 hours of ER observation, she was discharged with an outpatient appointment for herself and her daughter. However, she did not keep the initial appointment and was lost to follow-up.

Acute Mixed Dissociative Psychotic States

Many of the patients with mixed and transient dissociative and psychotic symptoms would fit the venerable diagnostic construct of *hysterical psychosis,* a condition studied extensively in the 19th century. Janet focused particularly on the traumatic origins of these symptoms and described their resolution through symptom stabilization, work on traumatic memories and fixed ideas, and, finally, conscious synthesis of the traumatic memories. As described above (section on History), at the end of the 19th-century dissociation-based theories of hysteria waned, the Freudian theories of hysterical symptoms became ascendant, and the Bleulerian view of schizophrenia came into prominence, subsuming hysterical psychosis. One dominant view was that individuals with hysterical psychosis had histrionic personality traits, limited ego resources, and were overwhelmed by conflicts, often sexual in nature, and/or acute losses. Other authors maintained that these individuals manifested a type of schizophrenia and others saw them more in the factitious/malingering spectrum, especially in forensic contexts. More recently, with the rediscovery of Janet's work and the development of the TM of dissociation, individuals with hysterical psychosis have been described as reacting to severe traumatic events, leading to alternative terminology such as *reactive dissociative psychosis.*

These combined dissociation-psychosis presentations must be distinguished from brief psychotic reactions, usually to traumatic stressors, without dissociative symptoms. In the North American literature, many of these patients may be conceptualized under the DSM-5-TR diagnosis of *brief psychotic disorder,* previously known in DSM-III and DSM-III-R as *brief reactive psychosis*. Symptoms of the latter condition overlap considerably with that of hysterical psychosis, as the diagnostic criteria for brief reactive psychosis specified that precipitating events included severe stressors such as a major loss or traumatic experiences such as combat. In DSM-5-TR, brief psychotic disorder has specifiers for occurrence after severe stress/trauma and without stress/trauma, respectively. Studies of brief psychotic disorder have not applied measures of dissociation and systematic studies of stressful or traumatic antecedents to brief psychotic disorder have not been conducted.

Turkish researchers describe hysterical psychosis as a common, well-known syndrome that is regularly diagnosed by Turkish psychiatrists, often presenting in the emergency department. Some Turkish authorities have reported case series of patients where hysterical psychosis was the presenting symptom cluster of dissociative identity disorder. The latter was recognized as the patient responded to treatment of the acute symptoms.

Cases of dissociative psychosis usually have a sudden onset; duration is typically 1 to 3 weeks, but in some cases may be longer. The individual's affect is often labile. Due to rapid shifts among different behavioral states, the individual may exhibit extreme ambivalence—doing and undoing some act in a psychotic or perseverative fashion. The psychotic and dissociative symptoms may have prominent posttraumatic content, which can be embedded in complex perceptual and somatosensory phenomena that occur automatically and uncontrollably (e.g., dissociative flashbacks to the traumatic event). In some cases, functional neurologic (conversion) symptoms may be the most prominent presenting sign(s). This condition causes a temporary impairment of daily functioning that typically requires short-term hospitalization. It is also associated with risk of suicidal behavior. A high prevalence of childhood abuse and/or neglect is often associated with dissociative psychosis.

Nonpsychotic cases of Example 3 are differentiated from adjustment disorder, ASD, and PTSD by the predominantly dissociative nature of the presentation and the absence of other symptoms of these disorders (e.g., hyperarousal, avoidance). There is no dissociative subtype of adjustment disorder and ASD can occur in the absence of dissociative symptoms. Example 3 presentations do not require a traumatic stressor.

Case descriptions of dissociative psychosis have included bizarre behavior, such as acting like an animal, and catatonic-like symptoms. Speech patterns may be disjointed and intermittent, sometimes giving the clinical impression of psychotic thought disorder. However, when the patient can speak coherently, there is no evidence of a psychotic thought disorder.

Differential Diagnosis of Dissociative Identity Disorder and Dissociative Psychosis. Some case series of individuals with dissociative psychosis have described symptoms that appear consistent with dissociative identity disorder. For example, a woman diagnosed with hysterical psychosis repeatedly hallucinated a second woman, with more resilient characteristics than herself, who conversed with her supportively about the life difficulties that preceded the psychotic episode.

Reports describe the experience of dissociative psychosis as consisting of multimodal hallucinosis; age regression; extensive dissociative amnesia; oneroid states; pseudodelirum/ pseudodementia; and delusional phenomena. However, in these accounts, the apparent delusions may be understood as related to, and usually symbolically condensing, traumatic experiences and intrapsychic conflicts that have generated the episode. Clinical experience suggests that most of these patients do not have a psychotic disorder but, with more extensive evaluation, will meet diagnostic criteria for dissociative identity disorder. In general, in dissociative identity disorder, despite delusionally separate and/or disoriented self-states, other self-states maintain reality testing and disavow the delusional beliefs. In superimposed dissociative psychosis, reality testing and relationship to reality is impaired across all self-states, with loss of reality testing, until/unless the psychosis is lysed.

Pathology and Laboratory Examination. Research on hysterical psychosis has documented high scores on standard measures of hypnotic capacity in individuals with this disorder. High hypnotizability distinguishes this group of patients from those with psychotic disorders, who generally have low scores on standard measures of hypnotizability.

In contrast to acute organic mental disorder (delirium), persons with dissociative psychosis do not exhibit findings that are characteristic of delirium on neuropsychiatric examination, laboratory tests, EEG, or brain imaging. They are characterized by dissociative symptoms, including amnesia, dissociative flashbacks, and disruptions of consciousness rather than by the waxing and waning of symptoms, cognitive deficits, and interpersonal impoverishment typically found in patients with delirium.

Treatment

There are no systematic studies of treatment of cases of Example 3, and treatment principles are derived from case series. *Ataques de nervios* and other folk illnesses fitting Example 3 may be characterized by suicidal or aggressive behaviors amid the acute dissociative episode. Restraining the person may be temporarily necessary. In many cases, the patient or family do not seek professional help. Paradoxically, if the triggering stressors are deemed minor by significant others or there are concerns about chronicity, the individual may be brought for psychiatric treatment. While comorbid symptoms and disorders (e.g., depression) can respond to psychotherapeutic and/or psychopharmacological interventions, the dissociative symptoms are more likely to respond to supportive-expressive psychotherapy that identifies the traumatic and/or stressful events that preceded the dissociative reaction, as well as the intense psychological conflicts that, almost invariably, have been generated in the context of the stressful events. Usually, supporting the patient as they “tell the story” of the stressful event(s) is highly therapeutic. Recent research finds support for trauma-informed cognitive-behavioral therapy, with or without narrative and psychodynamic modalities for individuals whose reactions were precipitated by traumatic exposure.

Treatment of dissociative psychosis follows the triphasic model: education to help the patient understand the disorder; supportive interventions to help the patient develop better control over symptoms; expressive interventions to give voice to distress over traumas, conflicts, and losses; transformation of reenactments into a coherent narrative, and return of adequate reality testing. Following Janet, modern case series have demonstrated the effectiveness of hypnotic interventions in the treatment of patients with dissociative psychosis, many of whom demonstrate high hypnotizability on standardized measures. Clinicians trained in hypnosis may find that assessment of hypnotizability aids in differential diagnosis and hypnotic interventions may be effective as an adjunct to psychotherapy for these patients.

Hypnotic interventions give these patients a greater sense of control over symptoms (and autohypnotic states); help the patient to understand symptoms as logical in the context of trauma and/or stressful events; and can provide imagery that may help the patient with affect regulation, symptom control, grief-work, mastery of traumatic material, and integration of these experiences for healing. Patients may also helpfully use self-hypnotic techniques to manage symptoms outside of psychotherapy.

Patients with dissociative identity disorder in an acute episode of dissociative psychosis should be treated for the underlying disorder. The clinician should provide the patient psychoeducation about acute dissociative/psychotic symptoms to reassure them that these are part of the dissociative disorder and not necessarily a manifestation of a comorbid psychotic disorder. The clinician should emphasize that treatment of the episode will follow the phasic trauma treatment model to understand what has engendered the acute symptoms. Patients may benefit from learning that medication is unlikely to have a major direct impact on symptoms but may help decrease the intensity of severe terror states and assist with sleep (see discussion of psychopharmacological treatments for dissociative identity disorder). The clinician should have an index of suspicion that the patient with dissociative identity disorder in an acute dissociative psychotic episode may be responding to a recent traumatic event such as a sexual assault that they cannot process in verbal form without psychotherapeutic interventions.

Ms. M, a 29-year-old patient with dissociative identity disorder was admitted to a psychiatric hospital by her therapist. The therapist reported that the patient had been struggling with safety issues and did not attend an emergency appointment. The therapist called 911 and the police had to forcibly enter the patient's home. The patient was lying in her bed, mute except for moaning, rocking back and forth, and was otherwise unresponsive. She was taken to the emergency department where medical, toxicology, and laboratory examination were within normal limits. The patient had superficial self-inflicted cuts on her arms, bruising on her legs, and cuts on her feet. Examined by the ED psychiatrist, she spoke in a robotic voice, and said she was seeing "lights flashing, colors spinning" and was "hearing so many voices, I can't make them out at all;" some voices were experienced inside her mind but others were "bouncing around the room." She saw "lots of faces," felt "my body just floating around," but also would moan and say, "it hurts" but could not explicate this further. She said her thoughts were "being sucked out of my mind" but was perplexed about this, yet no delusional explanation was elicited. She denied thought broadcasting or audible thoughts and was "scared and frightened." She reported that her radiator at home "wants to kill me," but had no insight or distance from this idea.

At times her thoughts appeared disorganized with blocking; at other times, thought process was coherent and goal directed. She reported intense urges "from somewhere" to "cut myself to pieces and die." She was admitted to the hospital and treated for "acute psychosis" with olanzapine 10 mgs by mouth daily and lorazepam 2 mg by mouth every 6 hours as needed, with no change in symptoms over a week other than increased sedation. She was seen by a consultant who attempted to explore the origins of her recent symptom exacerbation. With consistent focus on the patient's making sense of her experience, she reported a recent sexual assault by an "old friend" whom she had encountered at a bar, who may have drugged her drink. Taken to his house, she found herself being assaulted, felt very confused, and attempted to run away, cutting her feet. She reported that his grabbing her legs as she tried to run out of the house caused the bruising. She eventually escaped and found her way home. Then, she cut herself “for punishment for being so stupid.” She reported a history of being drugged repeatedly in childhood, particularly while being trafficked as part of a ring based in her family of origin. The hallucinations and other perceptual abnormalities, as well as the thought disorganization, were related to specific flashbacks of these experiences, apparently stimulated by the drugging and the rape. After talking about this, the hallucinations abated and the patient became calmer. She was given psychoeducation about psychotic-like dissociative symptoms. At the time of discharge, antipsychotic medication was discontinued and the patient appeared grounded, insightful, and oriented, without perceptual disturbances or hallucinations, other than her usual self-state voices and PTSD intrusive symptoms.

DISSOCIATIVE TRANCE DISORDER

Definition

DSM-IV-TR included pathologic trance and pathologic possession trance states in Appendix B as separate elements of a combined category of dissociative trance disorder, one of the “Criteria Sets and Axes Provided for Further Study.” Categories in this section of the Manual fell short of full inclusion in DSM-IV-TR as specified diagnoses but were included in the Appendix to stimulate research for possible incorporation in DSM-5. Pathologic dissociative possession states are included in DSM-5-TR under dissociative identity disorder, leading to its redefinition as having two variants: possession-form and non–possession-form, both understood as culturally patterned forms of distress. By contrast, data on Example 4, dissociative trance disorder, was deemed insufficient to include it in DSM-5-TR as a specific dissociative disorder or to subsume it under another dissociative disorder. In ICD-11, trance disorder is a specified dissociative disorder, which is classified together with possession trance disorder as a combined category. Support for trance disorder as a distinct diagnosis is based on research from diverse international settings (e.g., Turkey, India, Mozambique, Uganda). A main distinction between Example 4/trance disorder and pathologic dissociative possession trance presentations in both classification systems is the absence of identity alteration in the former, which is ascribed in the latter to the influence of a spirit, power, deity, or other spiritual entity. Moreover, individuals with possession-form presentations exhibit a wider range of dissociative behaviors which are attributed to the possession agent. However, while this distinction is clear conceptually, in practice, the line between trance and possession trance conditions often becomes blurred. Most reports of trance conditions describe experiences that precede the emergence of identity alteration in the affected person and could therefore be considered prodromal elements of possession trance conditions, rather than a separate disorder.

Diagnosis and Clinical Features

DSM-5-TR describes Example 4, dissociative trance disorder, as a temporary, marked alteration in the state of consciousness or loss of the customary sense of personal identity without change of identity. There is often a narrowing or complete loss of awareness of the immediate surroundings or a selective focus on stimuli within the environment. This may manifest as a profound unresponsiveness or insensitivity to environmental stimuli. In addition, the individual may display minor stereotypical behaviors (e.g., finger movements) of which they are unaware and/or are experienced as beyond their control. Some patients experience transient paralysis and/or loss of consciousness.

The description in ICD-11 is similar: pathologic trance is defined as a recurrent or single and prolonged marked alteration in the person’s state of consciousness or a loss of the normal sense of personal identity without the experience of being replaced by an alternative identity. Attention and awareness may be limited to, or concentrated upon, unusually narrow and selective aspects of the immediate environment and there is often a limited but repeated set of movements, postures, and utterances that are experienced as outside the person’s control.

Both the DSM-5-TR and ICD-11 definitions exclude presentations characterized by identity alteration, including those attributed to an external possessing agent. Moreover, in both manuals, trance states should only be considered symptomatic of a mental disorder when they are involuntary and unwanted, not accepted as a part of a collective cultural or religious practice, and result in significant distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning.

Research on trance conditions without identity alteration may combine individuals with trance states not associated with subsequent identity alteration (“ICD-11 trance disorder” or “DSM-5-TR Example 4”) and those whose trance states precede dissociative possession state experiences (possibly “prodromal” possession-form presentations). With this limitation in mind, non/pre-possession trance states in settings in Mozambique and Uganda have been associated with hearing voices, strange dreams or nightmares, restlessness, inability to speak, and elevated somatic symptoms (e.g., headaches, stomach pains), among others.

Pathology and Laboratory Examination. There are little systematic data on differential diagnosis of this example of other specified dissociative disorders. Patients with this condition may require neurologic evaluation, EEG, and brain imaging to rule out a seizure disorder, and cardiac workup to rule out hypotension and/or arrhythmias. The differential diagnosis of the abnormal movements in Example 4 may include essential tremor and Huntington disease. Although the latter may be associated with significant psychiatric psychopathology, it usually does not present with loss of awareness of surroundings until very late in the course when dementia is prominent. It runs in families and can be ruled out by genetic testing, if needed. Children with attention-deficit hyperactivity disorder may be hyperfocused on things that interest them, like video games or television, but do not manifest trance-like behavior apart from this. Many individuals can “tune out” parents, spouses, and others during family strife; however, this is not the same as the spontaneous, involuntary disorder of pathologic trance states. Patients with this condition may demonstrate high hypnotizability on standard hypnotizability testing, a finding which may be helpful in differential diagnosis.

Treatment

There are no systematic treatment studies of dissociative trance in the absence of pathologic dissociative possession states. The treatment of trance states in settings with developed concepts of possession illness usually follows healing practices for spirit possession. In cultural settings without a tradition of these possession trance healing practices, treatment may proceed by clarifying the nature of the trance states and their relationship to more ordinary phenomena such as daydreaming. Assessment of hypnotizability may also allow the clinician to produce the same symptoms the patient is experiencing with hypnotic induction. This may lead to an increased sense of control and may be sufficient to assist the patient in recognizing autohypnotic states and developing strategies to manage these. In more chronic cases, a supportive-expressive psychotherapy, similar to that for functional neurologic (conversion) disorder, may be most successful.

Ms. M, a married woman in her 50s, was seen in consultation for "passing-out attacks." She had had increasingly frequent episodes of grimacing, rapid eye-blinking, and piano-playing finger movements, accompanied by an "eye-roll," showing only the sclera, and falling to the ground in an unresponsive state, often for several hours at a time. Extensive work up showed no indication of seizures, other neurologic disorders, cardiac causes, and metabolic causes, among others. Repeated courses of antipsychotic medications and mood-stabilizers for "periodic catatonia" were ineffective and only caused problematic side effects. Anti-depressants helped with the patient's mood but the episodes persisted. The consultant performed a lengthy diagnostic interview and administered screening and diagnostic interviews for dissociative disorders, ruling out dissociative identity disorder. Although the patient reported "watching" herself as if at a distance during the episodes and experiencing them "as if something just comes over me that I cannot control," she did not meet criteria for depersonalization/derealization disorder.

The consultant discovered many current personal, marital, and family stresses and determined that frequency of episodes increased with higher levels of family discord. The patient reported a childhood history of severe verbal violence between her parents and directed at her and her siblings. She coped with this psychologically by "just leaving" and "tuning it all out." The patient was educated about autohypnosis and trance states and rapidly achieved deep hypnotic trance with a brief induction. Hypnotic interventions were able to reproduce each of the patient's symptoms as well as a "hidden observer" that remained aware of what was occurring. Over several sessions, the patient was able to learn self-hypnosis to reproduce symptoms and to alleviate them. She was delighted at this improved sense of control and returned to her outpatient providers for work on the family issues.

The patient returned to the consultant several years later, disabled by the same symptoms, with unresponsive episodes many times a day. She had stopped doing self-hypnosis and family problems had recrudesced. She was admitted to a specialized trauma disorders unit where, initially, she continued to have many episodes a day. Psychotherapy focused on viewing the trance episodes as a maladaptive coping strategy and challenging the patient to handle problems and difficult affects (anger, shame, sadness) without hypnotic evasions, likening this to an addiction to drugs or alcohol. Milieu interventions involved staff not engaging in efforts to “rescue” the patient from episodes and helping other patients also not attempt to rescue her by calling staff to intervene. Family therapy focused on psychoeducation and practical solutions to the many issues faced by the family. A strong recommendation was made for outpatient psychotherapy with a clinician proficient in hypnosis and outpatient family and marital therapy. At the time of discharge, the patient had not had a trance episode for over a week.

[1] Salvia is member of the mint family found in Mexico. A legal, unregulated drug, it is a potent hallucinogen whose leaves, stems, and seeds can be purchased online and smoked, infused into drinks, or swallowed. The active ingredient, salvinorin-A, binds to the kappa opiate receptor, producing a hallucinogenic experience lasting from 30 minutes to hours.

[2] “Ego state” is a term originally coined by the psychoanalyst Paul Federn, later expanded by John and Helen Watkins, as a general theoretical construct about the mind, psychotherapy, and the phenomenology of hypnosis. Here, the term “ego” is used differently from the various ways it has been used in psychoanalytic theory,

particularly psychoanalytic ego psychology. For the purposes of this chapter, an ego state can be thought of as a discrete self-state, differing from those of dissociative identity disorder by not being a relatively separate center of information processing and without an ongoing sense of itself, a body image, and a capacity for dissociated action.

21

Normal Sexuality and Sexual Disorders

21.1 Normal Human Sexuality and Sexual Dysfunctions

Virginia A. Sadock, M.D.

Sexuality is a significant factor in a person's mental health. It is relevant to identity, to self-esteem, to the formation and quality of intimate relationships, and to a subjective sense of well-being. One's sexuality is enmeshed with other personality factors, biologic factors, physical health, and the prevailing mores of the society in which a person lives. It includes a personal perception of one's gender, and it reflects developmental experiences with sex throughout the life cycle.

Sexual behavior is diverse. Normality is defined differently in various cultures and at different times in the same culture. Normal sexual behavior brings pleasure to oneself and is frequently directed toward the pleasure of a partner. It involves stimulation of the primary sex organs, often including coitus, and frequently leads to climax; it is devoid of inappropriate feelings of guilt or anxiety and is not compulsive. Recreational, as opposed to relational sex, including casual, premarital, and extramarital activity and masturbation, is normal in some contexts. Sexual thoughts and fantasies are an integral part of sexuality.

Sexuality has been studied by physicians and researchers over time. In the classical era, Hippocrates cited the clitoris as the site of female sexual arousal, the first physician historically recorded to have made that assessment. In the Middle Ages, Islamic physicians recommended coitus interruptus as a form of birth control. At the end of the Renaissance and the beginning of the Reformation, a linen sheath was devised as a condom, not for purposes of birth control, but as protection against syphilis. During the Victorian era, sexologists such as Havelock Ellis (Fig. 21.1–1) and Richard von Krafft-Ebing (Fig. 21.1–2) presented diverging perspectives on sexual behavior. During that same period, Sigmund Freud developed his innovative theories on libido, childhood sexuality, and the effects of the sexual impulse on behavior. In the modern era, the research of Alfred Kinsey, the work of William Masters and Virginia Johnson, and the development of drugs that prevent contraception, aid erection, and replace hormones that decrease with menopause and aging contributed to the development of an era of sexual liberality. Sex has also been a consistent source of motivation and a focus of interest to humankind in general. Depictions of sexual behavior have existed from the time of prehistoric cave drawings through Leonardo da Vinci's anatomical illustrations of intercourse to current pornographic sites on the internet.

The most recent developments in the field of sexuality involve changes in cultural/legal acceptance of behaviors formerly considered taboo or abnormal. There is more acceptance of transgender behavior; homosexuality, first dropped by the APA as a sexual disorder in 1973, is no longer a barrier to joining the military, nor is transgender status. The majority of Americans currently are in favor of same-sex marriage, and self-definitions of sexuality are less binary (homosexual/heterosexual, male/female) and more fluid. Physicians have proposed moving gender designation on birth certificates below the line of demarcation, which would prevent using the designation as proof of gender in legal situations. The *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (DSM-5) finds fantasies insufficient for a diagnosis of paraphilia but requires acting on the fantasy or impulse. Recent clinical reports include studies of sexual behavior in older adults that have helped breach the taboo against sex in the older adults. Studies of gender differences in response to sexual stimulation indicate that the sequential/linear response model first postulated by Masters and Johnson seems more reflective of male response but appears to be an insufficient model of the experience of many women. Current research is examining the effect of technology and events such as the pandemic on sexual behavior. Conservative trends are apparent in the overturn of Roe vs. Wade and in legislation by some state legislatures severely limiting access to abortion and limiting access to medical care of transgender youth.

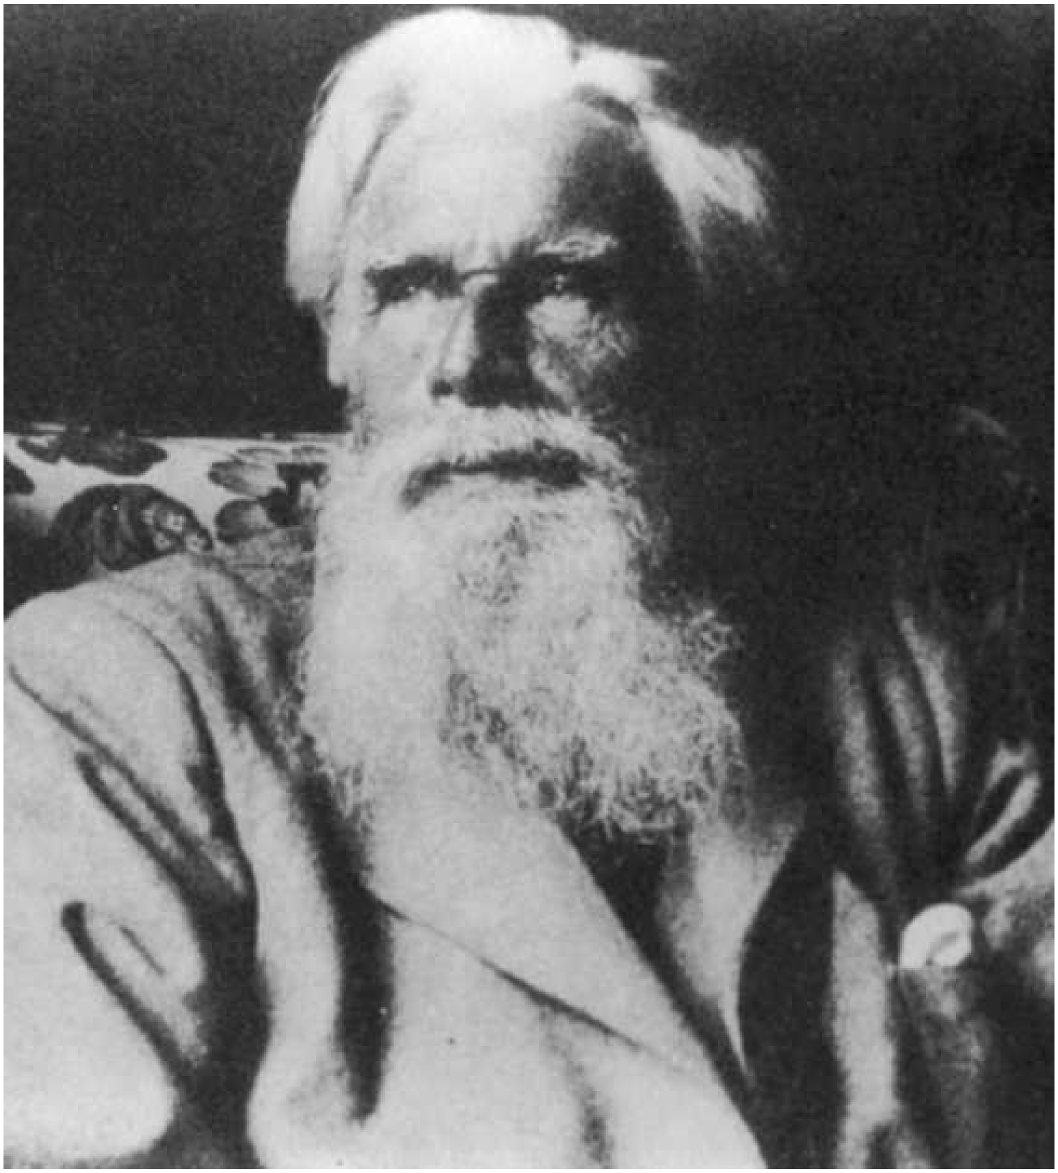

FIGURE 21.1–1. Havelock Ellis (1859–1939). In his book, *Studies in the Psychology of Sex* (1896), Ellis recorded examples of normal and abnormal sexuality. It remains a classic in the field of sexology. (Courtesy of New York Academy of Medicine.)

FIGURE 21.1–2. Richard von Krafft-Ebing (1840–1903), a psychiatrist who published a classic text, *Psyhopathia Sexualis* (1898), in which he documented every variation in sexuality, including zoophilia, necrophilia, urolagnia, and lust murder, among others. Case reports were so lurid and detailed that early editions were published in Latin. (Courtesy of New York Academy of Medicine.)

NORMAL SEXUALITY

Anatomical and Physiologic Bases

Knowledge about the organs of sexuality and the normal physiologic response of men and women is necessary for an informed understanding of sexual dysfunctions. In the 1960s, emphasis was placed on psychological and social contributions to dysfunction; in the 1990s, greater emphasis was placed on the genetic, neuroanatomical, and neurochemical model of human sexuality than on psychological and social factors. Currently, most clinicians believe an interplay of all these factors should be considered in treating sexual dysfunction.

Male Anatomy. The external genitalia of the normal adult man includes the penis, scrotum, testes, epididymis, and parts of the vas deferens. Internal components include the vas deferens, ejaculatory ducts, and prostate gland.

Freud referred to the penis as the executive organ of sexuality. In studies, male initiation of sexual interaction is usually found to be the determining factor in a couple's frequency of sexual connection. Since antiquity, culture has represented the penis in a variety of art forms. In ancient Greece, the cults of Dionysus, Priapus used the phallus as a recurrent symbol of fertility and rejuvenation. The word *penis* has been traced from the Latin, meaning variously "tail" or "to hang," and refers to the pendant position of the organ in its resting or flaccid state. The size of the penis varies within a fairly constant range, but sex researchers over the years have disagreed on the dimensions of the range. All agree, however, that concern over the size of the penis is practically universal among men. Masters and Johnson report a range of 7 to 11 cm in the flaccid state and 14 to 18 cm in the erect state. Of particular interest was their observation that the flaccid dimension bears little relation to the erect dimension, as a smaller penis erects proportionally more than a larger one.

Circumcision, a procedure in which the prepuce is surgically removed, has been practiced for centuries as a religious rite by Jews and Muslims and is a common medical procedure in the United States today. The circumcised penis, with its exposed glans, was once believed to be less sensitive because of the cornification of the epithelium. In laboratory studies, however, researchers have found no difference in tactile threshold between the circumcised penis and the uncircumcised penis. Intravaginally, the prepuce of the uncircumcised penis remains retracted behind the glans during penile thrusting, dispelling the myth that premature ejaculation may be more common in uncircumcised men because of increased stimulation caused by preputial movements. The most recent recommendation of the American Academy of Pediatrics states that there are clearer medical benefits to circumcision than previously recognized, including lessened ability to transmit cases of AIDS, syphilis, or gonorrhea, a lower incidence of penile cancer, and fewer genitourinary infections in the first year of life. They stop short of recommending circumcision and leave the decision of whether or not to circumcise to parents in consultation with their doctors. However, they encourage insurance companies to cover the procedure.

Ejaculation is the forceful propulsion of semen and seminal fluid from the epididymis, vas deferens, seminal vesicles, and prostate into the urethra. The dilation of the prostatic urethra and the passage of fluid into the penile urethra provides the man with a sensation of impending climax, the emission phase of the ejaculatory process. Indeed, once the prostate contracts, ejaculation is inevitable. The ejaculate is then propelled through the penile urethra by contractions of the striated pelvic and perineal muscles. This phase of ejaculation is essentially under somatic efferent control. The ejaculate consists of approximately one teaspoon (2.5 mL) of fluid and contains approximately 120 million sperm cells. It is believed that the larger the ejaculate, the more pleasurable the orgasm, but this belief is highly subjective. The sense of pleasure that accompanies orgasm is thought to be a cortical experience. Men who have had a prostatectomy and therefore no longer ejaculate report they still experience strong and satisfactory orgasms.

Female Anatomy. The external genitalia of the normal woman, also called the *vulva,* include the mons pubis, major and minor lips, clitoris, glans, vestibule of the vagina, and vaginal orifice. The internal system includes the ovaries, fallopian tubes, uterus, and vagina.

The clitoris is an erogenous female organ, only part of which is visible. Masters and Johnson described the clitoris as the primary female sexual organ because orgasm depends physiologically on adequate clitoral stimulation. Anatomically, the clitoris has a nerve net that is proportionally three times as large as that of the penis. The clitoris consists of the glans and the prepuce or clitoral hood. The clitoral prepuce is contiguous with the labia minora, and, during coitus, the penis does not stimulate the clitoris directly. Rather, penile thrusting exerts traction on the minor lips, which, in turn, stimulates the clitoris sufficiently for orgasm. During heightened excitement, just before orgasm, the clitoris retracts under the clitoral hood because of the contraction of the ischiocavernosus muscles.

Retracting, the clitoris moves away from the vaginal barrel, which makes clitoral–penile contact impossible. The size of the clitoris varies considerably and is unrelated to the sexual responsiveness of a particular woman.

Alfred Kinsey found that when women masturbate, most prefer clitoral stimulation. That finding was refined further by Masters and Johnson, who reported that women prefer the shaft of the clitoris to the glans because the glans is hypersensitive if stimulated excessively.

The word *vagina* comes from the Latin word meaning “sheath.” The vagina is usually collapsed, a potential rather than an actual space. Approximately 8 cm long, the vagina extends from the cervix of the uterus above to the vestibule of the vagina or vaginal opening below. In most virgins, a membranous fold, the hymen, separates the vestibule and opening from the rest of the vaginal canal. The mucous membrane lining the vaginal walls rests in numerous transverse folds. To accommodate the penis during sexual intercourse, the vagina expands in both length and width. After menopause, because circulating estrogen concentrations decrease, the vagina loses much of its elasticity

In 1950, Ernst Graefenberg described an area surrounding the female urethra in the anterior wall of the vagina that has come to be called the *G spot.* Approximately 0.5 to 1.0 cm in size, it becomes engorged during sexual stimulation. Many women report that stimulation of the area is highly pleasurable and, in some, can induce orgasm. Graefenberg believed that the tissue here was analogous to the prostate and might account for the spurt of fluid during orgasm reported by some women, similar to male ejaculation. Some women state that a vaginal orgasm is a different experience for them, providing different sensations than a clitoral orgasm. One explanation is that their pleasure is enhanced by the sense of closeness engendered by coitus. Another hypothesis is that these women climax in response to coital stimulation of the G spot.

Innervation of Sex Organs. Innervation of the sexual organs is mediated primarily through the autonomic nervous system (ANS). Penile tumescence occurs through the synergistic activity of two neurophysiologic pathways. A parasympathetic (cholinergic) component mediates reflexogenic erections via impulses that pass through the pelvic splanchnic nerves (S2, S3, and S4). A thoracolumbar, mainly sympathetic pathway transmits psychologically induced impulses. Both parasympathetic and sympathetic mechanisms are thought to play a part in relaxing the smooth muscles of the penile corpora cavernosa, which allows the penile arteries to dilate and causes the inflow of blood that results in penile erection. Relaxation of cavernosal smooth muscles is aided by the release of nitric oxide, an endothelium-derived relaxing factor. Clitoral engorgement and vaginal lubrication also result from parasympathetic stimulation that increases blood flow to genital tissue.

Table 21.1–1.
Responses of Sex Organs to Autonomic Nerve Impulses

Effector Organs	Adrenergic Impulses		Cholinergic Impulses
	Receptor Type	**Responses**	**Responses**
Urinary bladder			
Detrusor	β_2	Relaxation (usually)	Contraction
Trigone and sphincter	α_1	Contraction	Relaxation
Ureter

Adapted from Westfall TC, Macarthur H, Westfall DP. Neurotransmission: the autonomic and somatic motor nervous systems. In: Brunton L, Knollmann B, Hilal-Dandan R, eds. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. McGraw-Hill Education; 2018.

Evidence indicates that the sympathetic (adrenergic) system is primarily responsible for ejaculation. Through the hypogastric plexus, adrenergic impulses innervate the urethral crest, the muscles of the epididymis, and the muscles of the vas deferens, seminal vesicles, and prostate. Stimulation of the plexus causes emission. In women, the sympathetic system facilitates the smooth muscle contraction of the vagina, urethra, and uterus that occurs during orgasm.

The ANS functions outside of voluntary control and is influenced by external events (e.g., stress, drugs) and internal events (hypothalamic, limbic, and cortical stimuli). Considering these influences, it is not surprising that erection and orgasm are so vulnerable to dysfunction (Table 21.1–1).

Endocrinology. From the time of conception, hormones play a major role in human sexual development. Unlike the fetal gonads, which are under chromosomal influence, the fetal external genitalia are very susceptible to hormones. Testosterone mediates the development of the undifferentiated mesodermal Wolffian ducts into the male vas deferens, epididymis, and seminal vesicles. Dihydrotestosterone, produced from testosterone, induces the penis and scrotum. The raphe in men corresponds to the anatomical location of the vaginal orifice in women (Fig. 21.1–3).

Exogenous hormonal administration can cause external genital development inconsistent with the fetal sex gland development. For instance, if the pregnant mother receives sufficient exogenous androgen, a female fetus possessing an ovary can develop external genitalia resembling those of a male fetus. Fetal, maternal, or exogenous hormones administered to a pregnant woman may all affect the development of the external genitalia of the fetus. Deprived of male and female gonads and the respective hormones, testosterone, and estrogen, the human adult does not develop normal secondary sexual characteristics, is incapable of reproduction, and, in the case of the woman, does not develop a menstrual cycle.

Testosterone is the hormone believed to be connected with libido in both men and women. In men, stress is inversely correlated with testosterone blood concentration. Other factors, such as sleep, mood, and lifestyle influence circulating levels of the hormone. The release of testosterone in men is under the control of the hypothalamic–gonadal–pituitary axis. The hormone is secreted in a pulsatile manner and in a diurnal rhythm, with the highest levels occurring in the morning and the lowest levels in the evening. Normal concentrations range from 270 to

1,100 ng/dL. Decreased testosterone concentrations are apparent by age 50 years and decrease at the rate of approximately 100 ng/dL per decade. However, many healthy, aging men never become hypogonadal. It has also been suggested that the sensitivity of androgen receptor sites decreases in aging men.

FIGURE 21.1–3. Differentiation of male and female external genitalia from indifferent primordial. Male differentiation occurs only in the presence of androgenic stimulation during the first 12 weeks of fetal life. (Reprinted with permission from Rhoades RA, Bell DR. *Medical Physiology: Principles for Clinical Medicine*. 6th ed. Wolters Kluwer; 2022.)

Recent studies indicate that estrogen is also a factor in the male sexual response and that a decrease in estrogen in middle-aged males results in greater fat accumulation, just as it does in women. Progesterone mildly depresses desire in men and women, as do excessive prolactin and cortisol.

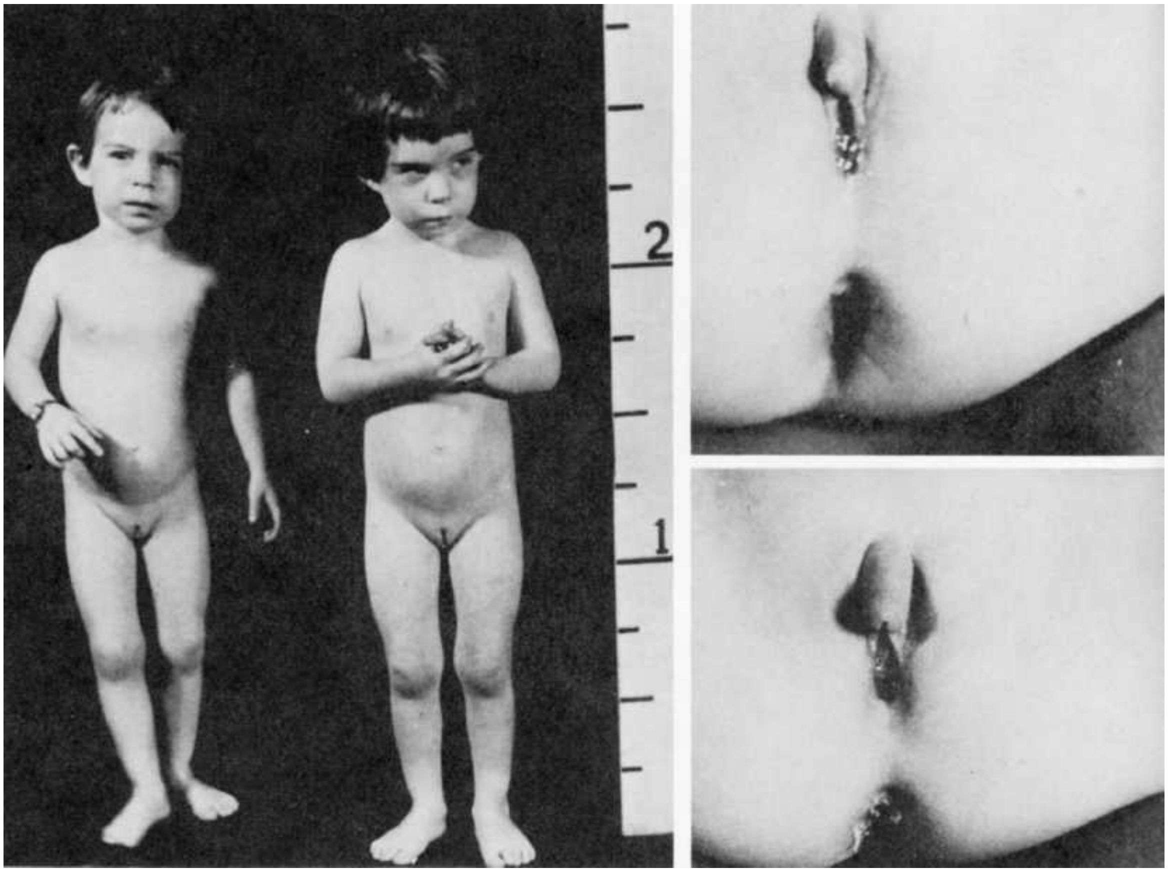

FIGURE 21.1–4. Twins born to a mother who received testosterone during pregnancy. Note the enlarged clitoris in each child. (Courtesy of Robert B. Greenblatt, M.D. and Virginia McNamarra, M.D.)

Androgen administered to men to address the loss of potency and loss of libido is usually unsuccessful unless testosterone concentrations are below normal, and administration to women may precipitate disturbing virilization. Many clinicians correct the hormone deficiency of the postmenopausal period with hormone replacement therapy (HRT). Testosterone has been used in combination with estrogen and progesterone in women who do not respond to estrogen alone. The combination is especially useful in treating headaches, depression, and reduced libido. Oxytocin is involved in pleasurable sensations during sex and is found in higher levels in men and women following an orgasm.

Diethylstilbestrol (DES), an androgenic steroid, was prescribed in the 1950s and 1960s for pregnant women with threatened abortion. However, the drug had untoward effects on the children (especially female children) born to these mothers. Reports of cervical and uterine abnormalities were reported in women, and reproductive tract abnormalities were reported in men. The children (called *DES daughters and sons*) organized a National DES Education Program sponsored by the National Cancer Institute to provide information on the potential medical problems confronting those born to DES mothers (Fig. 21.1–4).

Genetics. Genes are involved in gonadal differentiation, resulting in the formation of the bipotential gonad into either a testis or ovary. The best-defined gene in this process is *SRY* (sex-determining region of the Y chromosome), located on the short arm of the Y chromosome. Other genes also play a smaller role, such as *WT1* (Wilms tumor 1), *SF*-*1* (steroidogenic factor 1), *SOX9, DAX1,* and *MIS*-*12* (müllerian-inhibiting substance 12). Defects or mutations in these genes cause failures in gonadal differentiation that produce clinical syndromes known as *intersex disorders.* Figure 21.1–5 describes some genetic factors involved in the determination of male sex.

Central Nervous System and Sexual Behavior

Cortex. The cortex is involved both in controlling sexual impulses and in processing sexual stimuli that may lead to sexual activity. One study using positron emission tomography (PET) scans to monitor the brain activity of men in their 20s while they were shown various films, including a documentary, a comedy, and a sexually explicit film, found that some areas of the brain were more active during the sex film than they were during the other films. These areas included the orbitofrontal cortex, which is involved in emotions, the left anterior cingulate cortex, which is involved in hormone control and sexual arousal, and the right caudate nucleus, whose activity is a factor in whether sexual activity follows arousal.

FIGURE 21.1–5. A complex series of steps must occur in gonadal differentiation. A number of genes are critical to appropriate male genital development. *SRY* (sex-determining region of the Y chromosome), a gene on the short arm of the Y chromosome, is a testis-determining factor. The *SOX9* gene is also important in male sexual differentiation. *DAX1,* an orphan member of a nuclear hormone receptor family located on the X chromosome, interacts with steroidogenic factor 1 (*SF-1*). Other genes involved in male gonadal differentiation include the tumor-suppressor gene *WT1* (Wilms tumor 1), and the müllerian inhibiting substance gene (*MIS*) and its receptor, MIS-R.

Limbic System. Experimentation with animals has demonstrated that the limbic system is directly involved with elements of sexual functioning. In all mammals, the limbic system is involved in behavior required for self-preservation and the preservation of the species.

Chemical or electrical stimulation of various sites of the limbic system, the lower part of the septum and the contiguous medial preoptic area, the fimbria of the hippocampus, the mammillary bodies, and the anterior thalamic nuclei have all elicited penile erection.

The hippocampus is believed to influence genital tumescence and affect the regulation of the release of gonadotropins. Stimulation of the amygdala in primates initiates oral (chewing, lip-smacking) and then genital (penile erection) behavior. Researchers have stated that the closeness of these functions may derive from the evolutionary fact that the olfactory sense was strongly involved in both feeding and mating. They speculate that the evolution of the third subdivision of the limbic system may reflect a shift in importance from olfactory contact to visual communication in sociosexual behavior.

Studies of women have revealed that those areas activated by emotions of fear and anxiety are notably quiescent when the woman experiences an orgasm.

Brainstem. Brainstem sites exert inhibitory and excitatory control over spinal sexual reflexes. One site, the nucleus paragigantocellularis, has been identified as important in inhibitory control of climax-like responses in men and is suspected to be involved in female physiology as well. This nucleus projects directly to pelvic efferent neurons in the lumbosacral spinal cord, apparently causing them to secrete serotonin, which is known to inhibit orgasms. The lumbosacral cord also receives strong projections from other serotonergic nuclei in the brainstem, the raphe nuclei, pallidus, magnus, and parapyramidal region.

Brain Neurotransmitters. A vast array of neurotransmitters is produced by the brain, including dopamine, epinephrine, norepinephrine, and serotonin, among others. All affect sexual function. For example, an increase in dopamine is presumed to increase libido. Serotonin produced in the upper pons and midbrain is presumed to have an inhibitory effect on sexual function. Oxytocin, the neurohormone involved in the milk ejection reflex, is released with orgasm and is believed to reinforce pleasurable activities.

Spinal Cord. As described in the innervation of sex organs, sexual arousal and climax are ultimately organized at the spinal level. Sensory stimuli related to sexual function are conveyed via afferents from the pudendal, pelvic, and hypogastric nerves. These afferents terminate in the medial portions of the dorsal horn and in the medial central gray matter of the spinal cord. Several separate experiments suggest that sexual reflexes are mediated by spinal neurons in the central gray region of the lumbosacral segments.

BIOLOGIC DIFFERENCES BETWEEN THE SEXES

Hormonal Differences

The effects of estrogen in the female and androgen in the male are necessary for the development of ova and spermatozoa, respectively, and for potential fertility. They underlie and define the development of secondary sex characteristics at puberty. Both sexes initially synthesize androgens such as androstenedione or testosterone from acetate or cholesterol in the ovary and testes. Estrogen is then synthesized from the androgen. The two most potent forms of these hormones are estradiol and testosterone.

The defining hormonal difference between women and men is the quantity of these hormones present in the sexes: the testis makes approximately 7,000 ng of testosterone per day and converts one-quarter of 1% to estradiol. The ovary makes only 300 ng of testosterone per day and converts 50% of it to estradiol. Testosterone production in the ovary may vary during the menstrual cycle, but as testosterone production increases, so does the percentage of it, which is converted to estradiol. Overall, men make 20 times as much androgen as do women and women convert 200 times as much androgen to estradiol as do men. The contrasts are further emphasized because estrogen levels are measured in picograms, while androgen levels are measured in nanograms.

Intracellular hormone metabolism also contributes to sex differentiation. Many cells contain enzymes that can convert androgen to estrogen or testosterone to its more potent metabolite, dihydrotestosterone. Also present in certain cells are proteins, which influence the binding of sex hormones to elements affecting transcription sites in relevant DNA.

Ultimately, each tissue can develop an individual androgenic or estrogenic identity that might not be assumed, predicted, or distinguished on the basis of circulating hormone levels. These cellular identities may be particularly important in the brain and may have relevance to sexual behavior, sexual identity, partner choice, and brain dimorphism.

Genetic Differences

Human cells contain 23 pairs of chromosomes for a total of 46. There are 22 pairs of autosomes and 1 pair of sex chromosomes. The sex chromosomes are the X (female) chromosome and the Y (male) chromosome. These chromosomes determine biologic sex. Genetically, the normal male has a chromosomal 46XY karyotype, and the normal female has a 46XX karyotype. The X chromosome carries approximately 1,090 genes, while the human Y chromosome contains only about 80 genes. Further, the Y chromosome contains a unique class of genes in the male-specific region, particularly associated with testicular function. Also, the genes on the Y chromosome have twice the mutation frequency of those on the X chromosome.

The startling difference in the number of genes carried by a 2X woman as contrasted with a single X man is moderated by the fact that the second X chromosome in women is largely inactivated sometime before there are 20 cells in the blastocyst. However, 15% of the genes on the second X escape inactivation, and another 20% are only partially inactivated. The inactivated X chromosome is converted from a linear X into the Barr body, a little ball of genetically inert DNA.

Sex determination is induced by the different karyotypes. In the male, testis growth is induced by the sex-determining region of the Y chromosome. In the female, the follicle surrounding her oocytes is stabilized by the second X. Further differences in the ways the XX and XY genotypes influence early differentiation and later development are being studied.

PSYCHOSEXUALITY

Sexuality and total personality are so entwined that it is virtually impossible to speak of sexuality as a separate entity. The term *psychosexual* is therefore used to describe personality development and functioning, as these are affected by sexuality. *Psychosexual* applies to more than sexual feelings and behavior, and it is not synonymous with libido in the broad Freudian sense.

Freud’s generalization that all pleasurable impulses and activities are originally sexual has given lay people a somewhat distorted view of sexual concepts and has given psychiatrists a confused picture of motivation. For example, some oral activities are directed toward obtaining food, and others are directed toward achieving sexual gratification. Both activities are pleasure seeking and use the same organs, but they are not, as Freud contended, both necessarily sexual. Labeling all pleasure-seeking behaviors *sexual* obviates specifying precise motivation. People may also use sexual activities to gratify nonsexual needs, such as dependency, aggression, power, and status. Although sexual and nonsexual impulses may jointly motivate behavior, the analysis of behavior depends on understanding the underlying individual motivation and their interactions.

Sexuality is something more than physical sex, coital or noncoital, and something less than all behaviors directed toward gaining pleasure.

Psychosexual Factors

Sexuality depends on four interrelated psychosexual factors: sexual identity, gender identity, sexual orientation, and sexual behavior. These factors affect personality, development, and functioning.

Sexual identity is the pattern of a person's biologic sexual characteristics: chromosomes, external and internal genitalia, hormonal composition, gonads, and secondary sex characteristics. In normal development, these characteristics form a cohesive pattern that leaves individuals in no doubt about their sex.

Gender identity is an individual's sense of maleness or femaleness. By the age of 2 or 3 years, most children have a firm conviction that "I am a boy" or "I am a girl." Gender identity results from an almost infinite series of clues derived from experiences with family members, peers, and teachers and from cultural phenomena. For instance, male infants tend to be handled more vigorously, and female infants tend to be cuddled more. Fathers tend to be more aware of their sons' adolescent concerns than of their daughters' anxieties. Boys are more likely to be physically disciplined than girls are. A child's sex may affect parental tolerance for aggression and for reinforcement or extinction of activity and of intellectual, aesthetic, and athletic interests. Physical characteristics derived from a person's biologic sex (e.g., physique, body shape, and physical dimensions) interrelate with an intricate system of stimuli, including rewards, punishment, and parental gender labels, to establish gender goals. Studies of children with intersex conditions have drawn attention to a physiologic basis for gender identity. In particular, they have focused on the masculinization or feminization of the fetal brain. Some people claim a gender identity at odds with their biologic attributes. Others possess a fluid gender identity or one that does not fit into any recognized category, which they call "other."

Gender Role. Related to, and in part derived from, gender identity is gender role behavior. John Money and Anke Ehrhardt described gender role behavior as all those things that a person says or does to disclose themselves as having the status of boy or man, girl or woman, respectively. A gender role is not established at birth, but it is built up cumulatively through (1) experiences encountered and transacted through casual and unplanned learning, (2) explicit instruction and inculcation, and (3) spontaneously putting two and two together to sometimes make four and sometimes five. The usual outcome is a congruence of gender identity and gender role. Although biologic attributes are significant, the major factor in achieving the role the culture considers appropriate to a person's sex is learning.

Sexual orientation describes the object of a person's sexual impulses: heterosexual (opposite sex), homosexual (same-sex), or bisexual (both sexes). In some people, there is fluidity regarding objects of attraction. The majority of people have a heterosexual orientation. In the United States, 2.8% of men and 1.4% of women identify themselves as homosexual. These numbers are compatible with figures from Western European countries as well. However, a higher percentage of persons have had at least one same-sex experience in their lives. In addition, homosexuals congregate in urban areas, so the incidence of homosexuality in some large cities is 8% or 9%. A group of people have defined themselves as "asexual" and assert this as a positive identity. Some researchers believe this lack of attraction to any object is a manifestation of a desire disorder. Other people wish not to define their sexual orientation at all and avoid labels. Still, others describe themselves as polysexual or pansexual and claim a fluid identity. The percentage of people in the United States defining themselves as homosexual, bisexual, asexual, transgender or fluid has doubled in the past decade to 7%.

Sexual behavior includes desire, receptivity, fantasies, the pursuit of partners, autoeroticism, and all the activities engaged in to express and gratify sexual needs. It is an amalgam of psychological and physiologic responses to internal and external stimuli.

Table 21.1–2.
Female Sexual Response Cycle[a]

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
Mental	Lasts several minutes to several hours; heightened excitement before orgasm, 30 seconds to 3 minutes	3–15 seconds	10–15 minutes; if no orgasm, 0.5–1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Breasts	Nipple erection in two-thirds of women, venous congestion, and areolar enlargement; size increases to one-fourth more than normal	Breasts may become tremulous	Return to normal in approximately 0.5 hour
Clitoris	Enlargement in diameter of glans and shaft; just before orgasm, shaft retracts into prepuce	No change	Shaft returns to normal position in 5–10 seconds; detumescence in 5–30 minutes; if no orgasm, detumescence takes several hours

Labia majora	Nullipara: elevate and flatten against perineum Multipara: congestion and edema	No change	Nullipara: increase to normal size in 1–2 minutes Multipara: decrease to normal size in 10–15 minutes
Labia minora	Size increases two to three times more than normal; change to pink, red, deep red before orgasm	Contractions of proximal labia minora	Return to normal within 5 minutes
Vagina	Color change to dark purple; transudate appears 10–30 seconds after arousal; elongation and ballooning; lower third constricts before orgasm	3–15 contractions of lower third at intervals of 0.8 seconds	Ejaculate forms seminal pool in upper two-thirds; congestion disappears in seconds or, if no orgasm, in 20–30 minutes
Uterus	Ascends into false pelvis; labor-like contractions begin in heightened excitement just before orgasm	Contractions throughout orgasm	Contractions cease, and uterus descends to normal position
Other	Myotonia	Loss of voluntary muscular control	Return to baseline status in seconds to minutes
	A few drops of mucoid	Rectum: rhythmic	Cervix color and

secretion from Bartholin glands during heightened excitement	contractions of sphincter	size return to normal, and cervix descends into seminal pool
Cervix swells slightly and is passively elevated with uterus	Hyperventilation and tachycardia	

---

[a] A desire phase consisting of sex fantasies and desire to have sex often precedes the excitement phase.

Physiologic Responses

Sexual response is a true psychophysiological experience. Arousal is triggered by both psychological and physical stimuli; levels of tension are experienced both physiologically and emotionally, and with orgasm, normally a subjective perception of a peak of physical reaction and release occurs along with a feeling of well-being. Physical health, psychosexual development, psychological attitudes toward sexuality, and attitudes toward one's sexual partner are directly involved with and affect the physiology of human sexual response.

Normally, men and women experience a sequence of physiologic responses to sexual stimulation. In the first detailed description of these responses, Masters and Johnson observed that the physiologic process involves increasing levels of vasocongestion and myotonia (tumescence) and the subsequent release of the vascular activity and muscle tone as a result of orgasm (detumescence). In men, ejaculation is a normal part of the climax.

Refractory Period. Following orgasm, men experience a refractory period during which they cannot be restimulated to further arousal. The length of this period is age and situation dependent, with younger age and novel situations usually resulting in a shorter refractory period. Women do not have a refractory period and can experience multiple, successive orgasms.

Tables 21.1–2 and 21.1–3 describe the physiologic changes in the male and female that accompany sexual arousal, orgasm, and, subsequently, resolution back to the prestimulation baseline.

It is important to remember that the sequence of responses can overlap and fluctuate. In addition, a person's subjective experiences are as important to sexual satisfaction as the objective physiologic response. Figures 21.1–6 and 21.1–7 illustrate several possible patterns in the phases of the male sexual response and female sexual response, respectively.

Table 21.1–3.
Male Sexual Response Cycle[a]

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
Mental	Lasts several minutes to several hours; heightened excitement before orgasm, 30 seconds to 3 minutes	3–15 seconds	10–15 minutes; if no orgasm, 0.5 to 1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck, and can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Penis	Erection in 10–30 seconds caused by vasocongestion of erectile bodies of corpus cavernosa of shaft; loss of erection may occur with introduction of asexual stimulus—e.g., loud noise; with heightened excitement, size of glans and	Ejaculation: emission phase marked by three to four contractions of 0.8 seconds of vas, seminal vesicles, prostate; ejaculation proper marked by contractions of 0.8 seconds of urethra and ejaculatory spurt of 12–20 in at age 18, decreasing with	Erection: partial involution in 5–10 seconds with variable refractory period; full detumescence in 5–30 minutes

	diameter of penile shaft increase further	age to seepage at age 70	
Scrotum and testes	Tightening and lifting of scrotal sac and elevation of testes; with heightened excitement, 50% increase in size of testes over unstimulated state and flattening against perineum, signaling impending ejaculation	No change	Decrease to baseline size because of loss of vasocongestion; testicular and scrotal descent within 5–30 minutes after orgasm; involution may take several hours if no orgasmic release takes place
Cowper glands	2–3 drops of mucoid fluid that contain viable sperm are secreted during heightened excitement	No change	No change
Other	Breasts: inconsistent nipple erection with heightened excitement before orgasm	Loss of voluntary muscular control	Return to baseline state in 5–10 minutes
		Rectum: rhythmic contractions of sphincter	
	Myotonia: semispastic contractions of facial, abdominal,	Heart rate: up to 180 beats/min	

and intercostal muscles	Blood pressure: up to 40–100 mm systolic; 20–50 mm diastolic
Tachycardia: up to 175 beats/min	
Blood pressure: rises to 20–80 mm systolic; 10–40 mm diastolic	Respiration: up to 40 respirations/min
Respiration: increased	

[a] A desire phase consisting of sex fantasies and desire to have sex precedes the excitement phase.

Gender Differences in Desire and Erotic Stimuli

Sexual impulses and desires exist in men and women. In measuring desire by the frequency of spontaneous sexual thoughts, interest in participating in sexual activity, and alertness to sexual cues, males generally possess a higher baseline of desire than do women, which may be biologically determined. In the male, a desire phase consisting of sex fantasies and the desire to have sex usually motivates initiation of the sex act and precedes arousal. Motivations for having sex, other than desire, exist in both men and women but seem to be more varied and prevalent in women. In women, they may include a wish to reinforce the pair bond, the need for a feeling of closeness, a way of preventing the man from straying, or a desire to please the partner. Also, women, particularly those in long-term relationships, may experience desire synchronously with, or after the onset of, arousal rather than before it. Receptivity to the sex act seems to be as important a prelude to sexual behavior in women as desire. Recent studies have indicated variations in the male response pattern as well, primarily a conflation of the sensation of the experience of desire and arousal.

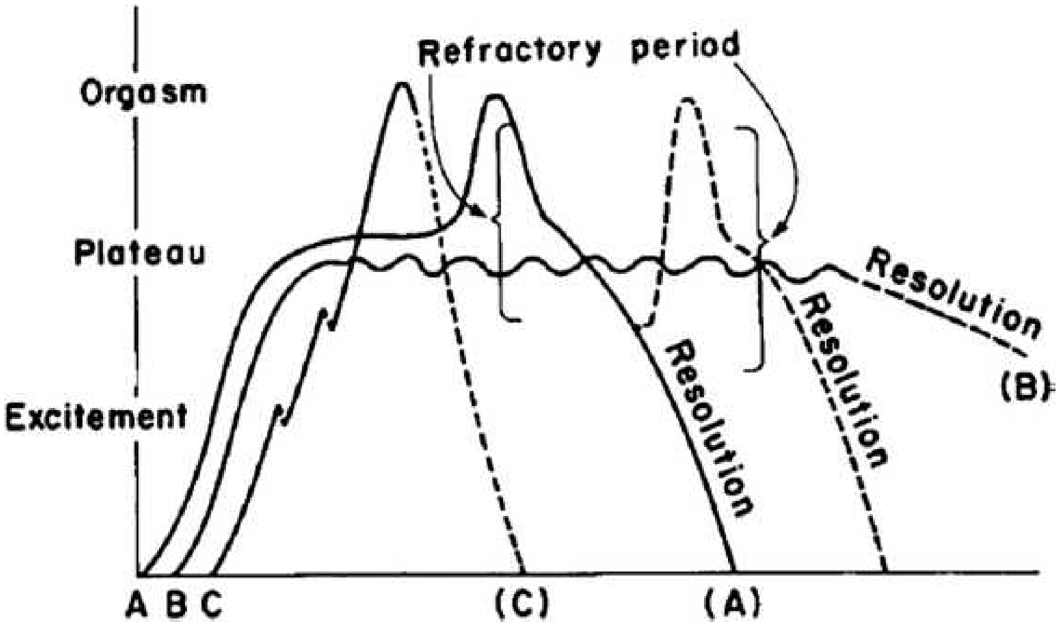

FIGURE 21.1–6. Male sexual response. An individual man may experience any of these three patterns (**A, B,** or **C**) during a particular sexual experience. (Reprinted with permission from Walker JI. *Essentials of Clinical Psychiatry*. JB Lippincott; 1985:276.)

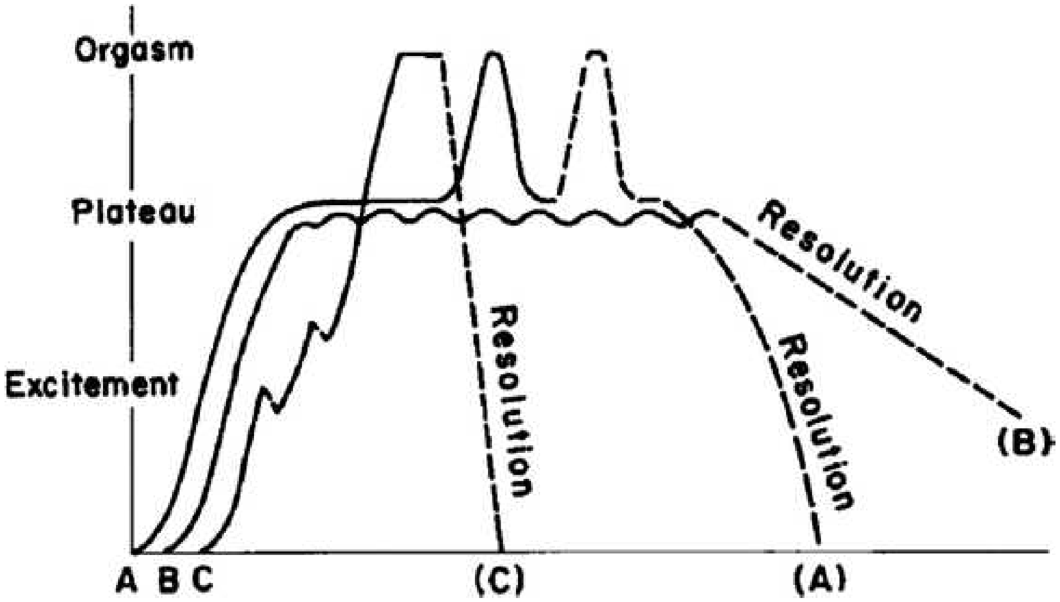

FIGURE 21.1–7. Female sexual response. An individual woman may experience any of these three patterns (**A, B,** or **C**) during a particular sexual experience. (Reprinted with permission from Walker JI. *Essentials of Clinical Psychiatry*. JB Lippincott; 1985:276.)

Although explicit sexual fantasies are common to both sexes, the external stimuli for the fantasies frequently differ for men and women.

Many men respond sexually to visual stimuli of nude or barely dressed women. Women report responding sexually to romantic stories with an erotic component and a hero whose passion for the heroine impels him toward a lifetime commitment to her. The popular erotic novel, Fifty Shades of Gray and the streaming series Bridgerton evolve with just such a plot.

A complex component of female sexuality is that a woman's subjective sense of arousal is not always congruent with her physiologic state of arousal. Specifically, her sense of excitement may reflect a readiness to be aroused rather than physiologic lubrication. Conversely, she may experience signs of arousal, including vaginal lubrication, without being aware of them or without wanting to act on them. These instances rarely occur in men.

Masturbation

Masturbation usually is a normal precursor of object-related sexual behavior and a form of sexual pleasure that generally lasts throughout a person's lifetime. No other form of sexual activity has been as universally practiced in spite of being severely condemned by many cultures for long periods of time.

In the classical period, Greco-Roman writers and medical authorities, such as Galen, recommended masturbation as a healthful practice for both men and women. The categorization of masturbation as sinful in Western culture derives from Judeo-Christian attitudes. Masturbation is sometimes called *onanism* after Onan in the Old Testament, who was slain for spilling his seed upon the ground. Many biblical scholars today posit that this punishment was not a result of his masturbation but because he did not obey Jehovah's commandment to take his brother's wife as his own. The prohibition against masturbation was reinforced by Christian Church fathers, particularly by St. Augustine, who preached celibacy and held that sex was appropriate only for purposes of procreation. Ambivalence about masturbation also existed in Eastern cultures. Some Hindus and the ancient Chinese believed that loss of semen resulted in a reduction of vital male essence. However, the prohibitive emphasis was on ejaculation and not on manipulation of the genitalia. Female masturbation was better tolerated or ignored.

For many years, science held attitudes toward masturbation that were as negative as many religious views. What had been viewed as sinful came to be seen as pathologic (Fig. 21.1–8). For example, in the 1800s, Krafft-Ebing believed that masturbation could lead to insanity. Currently, and in the second half of the 20th century, a liberal attitude toward sexual behavior, including masturbation, has prevailed but is consistently challenged by more restrictive thinking. Research by Kinsey in the 1940s into the prevalence of masturbation indicated that nearly all men and three-fourths of all women masturbate sometime during their lives.

Longitudinal studies of development show that sexual self-stimulation is common in infancy and childhood. Just as infants learn to explore the functions of their fingers and mouths, they learn to do the same with their genitalia. At about 15 to 19 months of age, both sexes begin genital self-stimulation. Pleasurable sensations result from any gentle touch to the genital region. Those sensations, coupled with an ordinary desire for exploration of the body, produce a normal interest in masturbatory pleasure at that time. Children also develop an increased interest in the genitalia of others—parents, children, and animals. As youngsters acquire playmates, the curiosity about their own and others' genitalia motivates episodes of exhibitionism or genital exploration. Such experiences, unless blocked by guilty fear or shaming, contribute to continued pleasure from sexual stimulation.

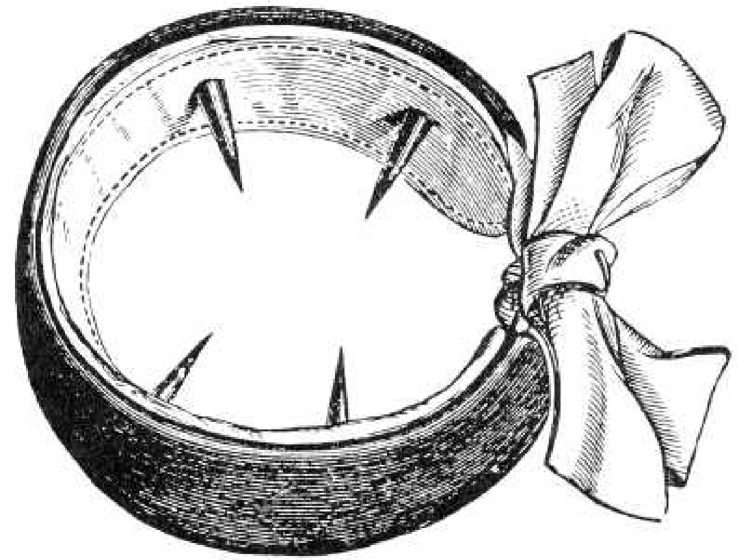

FIGURE 21.1–8. A four-pointed penile ring, which was used to prevent masturbation during the 19th century. This engraving shows how the ring was tied to the penis. (Reprinted with permission from Sadock BJ, Kaplan HI, Freedman AM. *The Sexual Experience*. Williams & Wilkins; 1976.)

With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity intensifies, and masturbation increases. Adolescents are physically capable of coitus and orgasm but are usually inhibited to some degree by social restraints. The dual and often conflicting pressures of establishing their sexual identities and controlling their sexual impulses produce a strong physiologic sexual tension in teenagers. Masturbation is a normal way to reduce that tension. In general, males learn to masturbate to orgasm earlier than females and masturbate more frequently. An important emotional difference between the adolescent and the youngster of earlier years is the presence of coital fantasies during masturbation in the adolescent. These fantasies are an important adjunct to the development of sexual identity; in the comparative safety of the imagination, the adolescent learns to perform the adult sex role. This autoerotic activity is usually maintained into the young adult years when it is normally replaced by coitus.

Couples in a sexual relationship do not abandon masturbation entirely. When coitus is unsatisfactory or is unavailable—because of illness or other unavailability of a partner—self-stimulation can serve an adaptive purpose, combining sensual pleasure and tension release. Studies of masturbation in married individuals have found different motivations for the activity in men and women. Partnered men frequently masturbate if they are dissatisfied with the partnered sex. For partnered women, masturbation is not a partner substitute but seems to indicate comfort with their own desires, reflects a high level of sexual interest, and often leads to increased partnered sex. In general, masturbation has come to be seen as a separate source of sexual pleasure that is not in conflict with partnered sex.

[Several studies found that in men, orgasm raised the serum prostate-specific antigen (PSA) significantly. Males scheduled for PSA tests should be advised not to masturbate (or have coitus) for at least 7 days prior to the examination.]

Moral taboos against masturbation have generated myths that masturbation causes mental illness, decreased sexual potency, or infertility. No scientific evidence exists to support such claims. Masturbation is a psychopathologic symptom only when it becomes a compulsion beyond an individual’s willful control. Then, it is a symptom of disturbance, not because it is sexual, but because it is compulsive. It is also symptomatic of a sexual problem when it is the main sexual activity of a person with an available intimate partner. Masturbation is probably a universal aspect of psychosexual development, and, in most cases, it is adaptive.

SEXUAL LEARNING AND SEXUAL BEHAVIOR

The sex drive is innate and varies in intensity in different people, but much sexual behavior is learned. Early sexual experiences, particularly those during puberty and early adolescence, can have an imprinting effect. If they are strongly associated with pleasure and release of tension, they are likely to be repeated, and the person is conditioned to a particular form of sexual expression. In the normal person, sexual learning and experimentation continue throughout the life cycle, the repertoire of sexual behavior expands, and the behaviors are compatible with cultural norms.

Sexual learning begins in childhood. In a broad sense, learning occurs through parent–child interaction, including the meeting of the infant's needs, cuddling, and the reinforcement or discouragement of gender-associated activities. Cuddling and appropriate physical touching engender emotional security and positive feelings in infants toward their bodies. That physicality lays the groundwork for a healthy body image that is a component of sexual self-esteem. A good body image also derives from mastery of early physical activity and a positive parental approach to tasks such as toilet training.

Genital self-stimulation is a normal activity of babies. It is particularly pronounced between the ages of 15 and 19 months, and it is part of the general interest of children in their bodies. The activity is reinforced by the pleasurable sensations it produces. Children also learn by watching the interaction of their parents. They observe demonstrations of physical affection (although usually not the sex act itself), and they are sensitive to the sexual undertone of flirtation, bantering, or seductive interchange.

Sexual learning in childhood is adversely affected by exploitative, abusive adults. Incestuous activity, with or without penetration, or sexual abuse by other adults (babysitters, other older relatives, teachers, coaches, etc.) is damaging to the child. It may precipitate sexual dysfunction in adult life, as well as promiscuity and problems with intimacy. It may produce delinquent activities and behavioral problems in adolescence, as well as learning problems in school.

Some children are inappropriately stimulated short of outright incest or genital fondling. They are the objects of extremely seductive parents. Termed *eroticized children,* they frequently become sexually precocious.

Children who view the *primal scene*—the term Freud used to describe a child seeing sex between their parents—may be traumatized. This is particularly the case if they interpret coital sounds and movements as physical aggression between the parents.

Adolescence

With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity is intensified.

In addition to masturbation, adolescents learn sexually through caressing and kissing with partners. In early adolescence, sex play may involve a partner of the same sex for a short period of time for heterosexuals as well as for homosexuals. Conversely, homosexuals may experiment with the opposite sex, although this occurs more frequently with lesbians than with homosexual men. Adolescence is also the time when one's body image becomes more definitive, and a sense of sexual adequacy and sexual desirability begins to develop. Peer acceptance by the same sex and by the opposite sex is of paramount importance. Engaging in sexual talk and jokes, kissing, stimulating genitalia manually or orally, experimenting with degrees of nudity, and experimenting with different partners or with one partner are part of the process of learning about sexuality. These experiences reinforce the adolescent's sense of being a sexual male or female. There is significant variability in the time of onset and degree of sexual experimentation in adolescence. It varies according to the physiology of the teen and the values of one's immediate community and peers.

In the recent past, a "hook-up" culture has been described among college students that is replacing traditional dating. It involves casual sex, that is, sex outside a committed or romantic relationship that may occur between friends ("friends with benefits") or as a one-night or occasional-night event. However, a survey contrasting student cohorts from 1988 to 1996 and 2004 to 2012 found respondents from the latter era did not report more sexual partners since age 18, more frequent sex, or more frequent sex partners during the previous year than respondents from the earlier era.

First Coitus

The first coitus is a rite of passage for both sexes. In the United States, the majority of people have experienced coitus by young adulthood, by their early 20s. In a study of people aged 18 to 59 years, over 95% had included coitus in their last sexual interaction.

The young man experiencing intercourse for the first time is vulnerable in his pride and self-esteem. Cultural myths still perpetuate the idea that he should be able to have an erection with no or little stimulation and that he should have an easy mastery over the situation, even though it is an act that he has never before experienced. Cultural pressure on the woman with her first coitus reflects the remaining cultural ambivalence about her loss of virginity, despite the current era of sexual liberality. This is demonstrated in the statistic that only 50% of young women use contraception during their first coitus, and of that 50%, an even smaller number use it consistently thereafter. Young women with a history of masturbation are more likely to approach intercourse with positive anticipation and confidence. Studies have shown that young women are more likely to enjoy their first coitus if it occurs in the context of a positive emotional relationship.

Adulthood

By their late 20s, 70% of men and 85% of women have formed a union, either exclusive cohabitation or marriage. The sexual impulse is catalytic in forming and maintaining adult love relationships. Ideally, a mature sexual relationship encompasses the capacity for intimacy and love for one’s partner.

As sexual access ceases to be problematic, more attention is focused on the activity itself. Interference with sexual activity arises from the time and energy required for the pursuit of careers, child-rearing, and other family and community obligations. Nonetheless, studies reveal a much higher frequency of sexual interaction among married persons than among single persons. The modal frequency for married persons is three times a month, with many couples relating sexually twice a week. The highest frequency of sexual interaction, four or more times a week, exists among cohabiting couples.

Kissing, intercourse, and masturbation are frequent sexual activities. Many adults have oral sex. Studies show that, although it is not a regular activity for most couples, many people are likely to engage in it occasionally throughout their lifetimes. The incidence of the practice of cunnilingus and fellatio are the same; the lifetime prevalence is 75% of sexually active people. Anal sex is not part of the regular sexual practices of most Americans. However, the incidence of the activity is rising. In one study, 35% of heterosexual men and 30% of heterosexual women reported having anal sex when asked about their sexual activities during the preceding year. In general, a graph of sexual practices does not form a bell curve. Most curves of sexual behavior are strongly skewed, with many persons indulging in a particular behavior or, conversely, very few people doing so.

Middle Age

During middle age, the frequency of marital intercourse may decline. The rates of interaction depend more on male interest, and the middle-aged man may devote much of his energy to his career at this point. The decline in sexual interaction often reflects the de-eroticization of the woman because of her wife–mother role. Familiarity also contributes to a decreased passion, and some men have difficulty connecting marital sexual activity with the erotic scripts they elaborated during their adolescence. Conversely, a couple's experience of each other makes them comfortable and augments their skill at mutual arousal. For women, interest in sexual competence typically increases at this time. A woman's erotic pleasure and sexual commitment are strongly connected to feelings of attachment toward her partner and the security of being in a loving relationship.

With late middle age, the biologic drive decreases in intensity. It takes the man longer to reach orgasm, he has a longer refractory period, and he requires more stimulation to achieve an erection. The woman must adjust to the hormonal fluctuations of her perimenopausal years, and she, too, requires more stimulation to become aroused. Although medications are available to address these specific physiologic changes, they do not eliminate all need to adjust to the aging process. In terms of family dynamics, children often leave the house for work or further education at this time. This fact plus freedom from concern regarding unwanted pregnancy may enhance sexual activity for persons who have more time to direct attention toward each other and renew their life as a couple.

However, middle age is the period of rising extramarital activity, although the frequencies of such occurrences are low—75% of men and

85% of women remain faithful throughout the lifetime of their marriages. Daniel Offer has explained that the patterning of extramarital sexual activity for both sexes continues to express earlier patterns of psychosexual development:

> For men, it predominantly has the capacity for detachment that in adolescence was directly related to the pursuit of sexual fantasies and the homosocial validation of masculinity. For women, on the other hand, it resembles a quest for circumstances that justify and confirm a romantic self-image rather than a quest for orgasms.

In the context of a loving, communicative, and committed relationship, a decreased frequency of sexual interaction does not herald the onset of extramarital affairs or threaten the stability of the marriage.

Old Age

In the last two decades, coitus has also been a part of the sexual repertoire of older adults due to the development of sildenafil-type drugs, which facilitate erections in men, and hormonally enhanced creams or hormonal pills, which counteract vaginal atrophy in postmenopausal women. Prior to the development of these drugs, and still today, many older adults enjoyed gratifying sex play, exclusive of coitus. An aversion to the idea of sex in the older adults persists in today’s culture. A man who had coitus with his wife while she was in a nursing home and suffered from a degree of dementia was accused by his stepchildren of sexual assault and brought to trial. He was found innocent.

An estimated 70% of men and 20% of women over age 60 years are sexually active. Recent studies have found that three in four people aged 57 to 64 years, two in four people aged 64 to 75 years, and one in four people aged 75 to 85 years had sexual intercourse in the year before the study. Of interest is that the reported frequency of intercourse, two or three times a month, is the same as the frequency reported by young and middle-aged adults. Expected physiologic changes in men include a longer time for an erection to occur, decreased penile turgidity, and ejaculatory seepage; in women, decreased vaginal lubrication and vaginal atrophy are associated with lower estrogen levels. Illness and medications can adversely affect sexual behavior. However, many older adults engage in sexual behavior exclusive of coitus which provides them with physical connection and satisfaction.

In studies, approximately half of older sexually active people aged 59 to 85 years report one or more sexual dysfunctions. Women report problems of low desire, difficulty with lubrication, and inability to climax. Among men, erectile disorder is the most commonly reported dysfunction. About 14% of older men report using medications or supplements to improve their erections. The factors contributing to continuing sex life in older adults include the presence of a partner, the absence of severe illness, and a history of sexual activity in young and middle adulthood. Physicians should include sexual behavior in their review of systems with older age patients since the majority of people in this age group will not bring up their concerns unless their doctor initiates the discussion. One study reported that over 85% of older adults would like doctors to include questions about sex during routine visits.

LOVE AND INTIMACY

Freud postulated that psychological health could be determined by a person's ability to function well in two spheres, work, and love. A person able to give and receive love with a minimum of fear and conflict has the capacity to develop genuinely intimate relationships with others. A desire to maintain closeness to the love object typifies being in love. Mature love is marked by intimacy that is a special attribute of the relationship between two persons. When involved in an intimate relationship, the person actively strives for the growth and happiness of the loved person. Sex frequently acts as a catalyst in forming and maintaining intimate relationships. The quality of intimacy in a mature sexual relationship is what Rollo May called "active receiving," in which a person while loving, permits themselves to be loved. May describes the value of sexual love as an expansion of self-awareness, the experience of tenderness, an increase of self-affirmation and pride, and sometimes, at the moment of orgasm, loss of feeling of separateness. In that setting, sex and love are reciprocally enhancing and healthily fused.

Some persons experience conflicts that prevent them from fusing tender and passionate impulses. This can inhibit the expression of sexuality in a relationship, interfere with feelings of closeness to another person, and diminish a person's sense of adequacy and self-esteem. When these problems are severe, they may prevent the formation of, or commitment to, an intimate relationship.

Sex and the Law

Medicine and the law both assess the impact of sexuality on the individual and society and determine what healthy or legal behavior is. Appropriateness or legality of sexual behavior, however, is not always viewed the same way by professionals in both disciplines. The issues at the interface of sexual science and the law often are emotionally charged and reflect cultural divisions about acceptable sexual mores. They include attitudes about abortion, pornography, prostitution, sex education, the homosexual and transgender community, the treatment of sex offenders, and the right to sexual privacy, among other issues. Laws regarding these issues (e.g., criminalization of oral or anal sex by consenting adults or the need for parental permission by minors who are requesting an abortion) vary from state to state.

Taking a Sex History

A sex history provides important information about patients, regardless of the presence of a sexual disorder or whether that is the patient's chief complaint. The information can be gradually obtained as therapy progresses and through open-ended questions. It is important for the interviewer to be nonjudgmental and sensitive to many patients' embarrassment in discussing sexual issues. As part of the sexual history, information regarding safe sex practices, sexually transmitted diseases, sexual orientation, gender identity, and history of any sexual abuse must be ascertained. The percentage of sexual abuse survivors seen in sex therapy programs is higher than that in the general population. The outline in Table 21.1–4 provides a guide to areas to be covered and a structure that can be used when time is limited.

Sexual Dysfunctions

The essential features of sexual dysfunctions are inhibition, specifically, an inability to respond to sexual stimulation physiologically or psychologically, or the experience of pain during the sexual act. The pain may have a physiologic, psychological, or mixed etiology. Dysfunction can be defined by a disturbance in the subjective sense of pleasure usually associated with sex or by objective performance.

According to the 11th revision of the *International Classification of Diseases* (ICD-11), sexual dysfunctions are syndromes that refer to a person's difficulty "experiencing personally satisfying, non-coercive sexual activities." The definition acknowledged the complex nature of the sexual response, incorporating psychological, interpersonal, social, cultural, and physiologic factors, and notes that any one of these factors can affect the response.

Definition

In the DSM-5, sexual dysfunctions include male hypoactive sexual desire disorder, female sexual female interest/arousal disorder, erectile disorder, female orgasmic disorder, delayed ejaculation, early (premature) ejaculation, genitopelvic pain/penetration disorder, substance/medication-induced dysfunction, other specified sexual dysfunction, and unspecified sexual dysfunction. Sexual dysfunctions are diagnosed only when they are a major part of the clinical picture. If more than one dysfunction exists, they should all be diagnosed. Sexual dysfunctions can be lifelong or acquired, generalized or situational, and result from psychological factors, physiologic factors, and combined factors, and numerous stressors, including prohibitive social mores, health and partner issues, and relationship conflicts. If the dysfunction is attributable entirely to a medical condition, substance use, or adverse effects of medication, then sexual dysfunction due to a general medical condition or substance-induced dysfunction should be diagnosed. In DSM-5, the specification of severity of the dysfunction is indicated by noting whether the symptomatology or the patient’s distress is mild, moderate, or severe.

Sexual dysfunctions are frequently associated with other mental disorders, such as depressive disorders, anxiety disorders, personality disorders, and schizophrenia. In many instances, the sexual dysfunction may be diagnosed in conjunction with another psychiatric disorder. If the dysfunction is largely attributable to an underlying psychiatric disorder, only the underlying disorder should be diagnosed. Sexual dysfunctions are usually self-perpetuating, with the patient increasingly subject to ongoing performance anxiety and a concomitant inability to experience pleasure. In relationships, the sexually functional partner may reacts with distress or anger due to feelings of deprivation or a fear that they are an insufficiently attractive or adequate sexual partner. In such cases, the clinician must consider whether the sexual problem preceded or arose from relationship difficulties and weigh whether a diagnosis of sexual dysfunction relevant to relationship issues is appropriate.

The sexual problem offers the psychiatrist a perspective on the person’s capacity to give and receive pleasure, to love and be loved, to be psychologically intimate, and to maintain some degree of sexuality through the vicissitudes of life.

Similar disorders exist among both homosexual and heterosexual partners, with variations imposed by anatomical differences. For example, although penile–vaginal dysfunction cannot be described among homosexuals, penile–anal dysfunction may occur. Regardless of sexual orientation, the physiologic response to sexual stimulation applies equally to same-sex and heterosexual partners, and the methods and principles for treatment are essentially similar.

Rating Scales

Several questionnaires are available to assess sexual function, in addition to the assessments made following the taking of a sexual history. They were developed primarily to evaluate illness or medication-related effects on sexual functioning. The most commonly used scales are the Arizona Sexual Experience Scale, the Brief Sexual Function Questionnaire, the Changes in Sexual Functioning Questionnaire, the Derogatis Sexual Function Inventory, and the Rush Sexual Inventory. The scales vary in length, reliability, validity, and method of administration. Some are rated by the patients themselves, others by the therapist. The formats include structured and semistructured approaches. The scales differ in the number of symptoms assessed, the dysfunctions they target, and the time frame they cover.

DESIRE, INTEREST, AND AROUSAL DISORDERS

Male Hypoactive Sexual Desire Disorder

This dysfunction is characterized by a deficiency or absence of sexual fantasies and desire for sexual activity for a minimum duration of approximately 6 months (Table 21.1–5). Men for whom this is a lifelong condition have never experienced many spontaneous erotic/sexual thoughts. Minimal spontaneous sexual thinking or minimal desire for sex ahead of sexual activity is not considered a diagnosable disorder in women, particularly if the desire is triggered during the sexual encounter.

Also, some men and women define themselves as being asexual. They are not distressed by a lack of desire and feel they are erroneously pathologized if this diagnosis is applied to them. A claim of asexuality occurs among women more frequently than among men. Some people define themselves as being on the “ace” (short for asexual) spectrum, which includes graysexuals, a person who rarely experiences sexual attraction, and demisexuals, one who experiences sexual attraction only after forming an intimate bond. There is controversy as to whether asexuals are likely to be aromantic—not interested in falling in love. The reported prevalence of low desire is greatest at the younger and older ends of the age spectrum, with only 2% of men aged 26 to 44 years affected by this disorder. A reported 6% of men aged 18 to 24 years and 40% of men aged 66 to 74 years have problems with sexual desire. Some men may confuse decreased desire with decreased activity. Their erotic thoughts and fantasies are undiminished, but they no longer act on them due to health issues, unavailability of a partner, or concern about another sexual dysfunction such as erectile disorder.

Table 21.1–4. Taking a Sex History

- I. Identifying data
  - A. Age
  - B. Sex
  - C. Occupation
  - D. Relationship status—single, married, number of times previously married, separated, divorced, cohabiting, serious involvement, casual dating (difficulty forming or keeping relationships should be assessed throughout the interview)
  - E. Sexual orientation—heterosexual, homosexual, or bisexual (this may also be ascertained later in the interview)
- II. Current functioning
  - A. Unsatisfactory to highly satisfactory
  - B. If unsatisfactory, why?
  - C. Feelings about partner satisfaction
  - D. Dysfunctions?—e.g., lack of desire, erectile disorder, inhibited female arousal, anorgasmia, premature ejaculation, retarded ejaculation, pain associated with intercourse (dysfunction discussed below)
  - 1. Onset—lifelong or acquired
    - a. If acquired, when?
    - b. Did onset coincide with drug use (medications or illegal recreational drugs), life stresses (e.g., loss of job, birth of child), interpersonal difficulties?
  - 2. Generalized—occurs in most situations or with most partners
  - 3. Situational
    - a. Only with current partner
    - b. In any committed relationship
    - c. Only with masturbation
    - d. In socially proscribed circumstance (e.g., affair)
    - e. In definable circumstance (e.g., very late at night, in parental home, when partner initiated sex play)
  - E. Frequency—partnered sex (coital and noncoital sex play)
  - F. Desire/libido—how often are sexual feelings, thoughts, fantasies, dreams, experienced (per day, week, etc.)?
  - G.

Description of typical sexual interaction

1. Manner of initiation or invitation (e.g., verbal or physical? Does same person always initiate?)
2. Presence, type, and extent of foreplay (e.g., kissing, caressing, manual or oral genital stimulation)
3. Coitus? Positions used?
4. Verbalization during sex? If so, what kind?
5. Afterplay? (whether sex act is completed or disrupted by dysfunction); typical activities (e.g., holding, talking, return to daily activities, sleeping)
6. Feeling after sex: relaxed, tense, angry, loving

H. Sexual compulsivity? (intrusion of sexual thoughts or participation in sexual activities to a degree that interferes with relationships or work, requires deception, and may endanger the patient)

III. Past sexual history

A. Childhood sexuality

1. Parental attitudes about sex—degree of openness or reserve (assess unusual prudery or seductiveness)
2. Parents' attitudes about nudity and modesty
3. Learning about sex
   a. From parents (Initiated by child's questions or parent volunteering information? Which parent? What was child's age?)? Subjects covered (e.g., pregnancy, birth, intercourse, menstruation, nocturnal emission, masturbation)?

b. From books, magazines, or friends at school or through religious group?

c. Significant misinformation

d. Feeling about information

4. Viewing or hearing primal scene—reaction?
5. Viewing sex play or intercourse of person other than parent
6. Viewing sex between pets or other animals

B. Childhood sex activities

1. Genital self-stimulation before adolescence—age? Reaction if apprehended?
2. Awareness of self as boy or girl—bathroom sensual activities (regarding urine, feces, odor, enemas)?
3. Sexual play or exploration with another child (playing doctor)—type of activity (e.g., looking, manual touching, genital touching)?

Reactions or consequences if apprehended (by whom?)?

IV. Adolescence
   A. Age of onset of puberty—development of secondary sex characteristics, age of menarche for girl, wet dreams or first ejaculation for boy (preparation for and reaction to)
   B. Sense of self as feminine or masculine—body image, acceptance by peers (opposite sex and same-sex), sense of sexual desirability, onset of coital fantasies
   C. Sex activities
   1. Masturbation—age begun? Ever punished or prohibited? Method used, accompanying fantasies, frequency (questions about masturbation and fantasies are among the most sensitive for patients to answer)?
2. Homosexual activities—ongoing or rare and experimental episodes? Approached by others? If homosexual, has there been any heterosexual experimentation?
3. Dating—casual or steady; description of first crush, infatuation, or first love
4. Experiences of kissing, necking, petting ("making out" or "fooling around"), age begun, frequency, number of partners, circumstances, type(s) of activity
5. Orgasm—when first experienced (may not be experienced during adolescence)? With masturbation, during sleep, or with partner? With intercourse or other sex play? Frequency?
6. First coitus—age, circumstances, partner, reactions (may not be experienced during adolescence), contraception and/or safe sex precautions used

V. Adult sexual activities (may be experienced by some adolescents)
   A. Premarital sex
   1. Types of sex play experiences—frequency of sexual interactions, types and number of partners
   2. Contraception and/or safe sex precautions used
   3. First coitus (if not experienced in adolescence)—age, circumstances, partner
   4. Cohabitation—age begun, duration, description of partner, sexual fidelity, types of sexual activity, frequency, satisfaction, number of cohabiting relationships, reasons for breakup(s)

    5. Engagement—age; activity during engagement period with fiancé(e), with others; length of engagement
  B. Marriage (if multiple marriages have occurred, explore sexual activity, reasons for marriage, and reasons for divorce in each marriage)
    1. Types and frequency of sexual interaction—describe typical sexual interaction (see above). Satisfaction with sex life? View of partner's feeling.
    2. First sexual experience with spouse—when? What were the circumstances? Was it satisfying? Disappointing?
    3. Honeymoon—setting, duration, pleasant or unpleasant, sexually active? Frequency? Problems? Compatibility?
    4. Effect of pregnancies and children on marital sex
    5. Extramarital sex—number of incidents, partner, emotional attachment to extramarital partners? Feelings about extramarital sex
    6. Postmarital masturbation—frequency? Effect on marital sex?
    7. Extramarital sex by partner—effect on interviewee
    8. Ménage à trois or multiple sex (swinging) (polyamony)
    9. Areas of conflict in marriage (e.g., parenting, finances, division of responsibilities, priorities)

VI. Sex after widowhood, separation, divorce—celibacy, orgasms in sleep, masturbation, noncoital sex play, intercourse (number of and relationship to partners), other

VII. Special issues
  A. History of rape, incest, sexual, or physical abuse
  B. Spousal abuse (current)
  C. Chronic illness (physical or psychiatric)
  D. History or presence of sexually transmitted diseases
  E. Fertility problems
  F. Abortions, miscarriages, or unwanted or illegitimate pregnancies
  G. Gender identity conflict—(e.g., transsexualism, wearing clothes of opposite sex)
  H. Paraphilias—(e.g., fetishes, voyeurism, sadomasochism)

Table 21.1–5.

DSM-5 Diagnostic Criteria for Male Hypoactive Sexual Desire Disorder

A. Persistently or recurrently deficient (or absent) sexual/erotic thoughts or fantasies and desire for sexual activity. The judgment of deficiency is made by the clinician, taking into account factors that affect sexual functioning, such as age and general and sociocultural contexts of the individual’s life.

B. The symptoms in criterion A have persisted for a minimum duration of approximately 6 months.

C. The symptoms in criterion A cause clinically significant distress in the individual.

D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify whether:

Lifelong: The disturbance has been present since the individual became sexually active.

Acquired: The disturbance began after a period of relatively normal sexual function.

Specify whether:

Generalized: Not limited to certain types of stimulation, situations, or partners.

Situational: Only occurs with certain types of stimulation, situations, or partners.

Specify current severity:

Mild: Evidence of mild distress over the symptoms in criterion A.

Moderate: Evidence of moderate distress over the symptoms in criterion A.

Severe: Evidence of severe or extreme distress over the symptoms in criterion A.

A variety of causative factors are associated with low sexual desire. Patients with desire problems often use inhibition of desire defensively to protect against unconscious fears about sex. Sigmund Freud conceptualized low sexual desire as the result of inhibition during the phallic psychosexual phase of development and of unresolved oedipal conflicts. Some men, fixated at the phallic stage of development, are fearful of the vagina and believe they will be castrated if they approach it. Freud called this concept vagina dentata. He theorized that men avoid contact with the vagina when they unconsciously believe that the vagina has teeth. Lack of desire can also result from chronic stress, anxiety, or depression.

The presence of desire depends on several factors: biologic drive, adequate self-esteem, the acceptance of sexuality as a positive attribute, previous good experiences with sex, the availability of an appropriate partner, and a good relationship in nonsexual areas with one's partner. Damage to any of those factors may result in diminished desire.

Hypoactive *sexual* desire disorders often become manifest during puberty and may be a lifelong condition. A general medical workup should be conducted to rule out a medical cause, which, if present, would be, according to DSM-5, diagnosed as hyposexual desire disorder due to a general medical condition.

A 20-year-old college student presented with a complaint of insufficient desire for sex. He stated that he was bisexual but complained, "I wish I could be more interested in women." During the course of the interview, he revealed that he had sexual fantasies about men dating from his adolescence and that he masturbated regularly to erotic visual stimuli involving men. He had fears of erectile dysfunction prior to coitus with women but did not experience these fears prior to sexual interaction with men. These interactions involved manual and oral sex play but no penetration. He connected with men online and had not disclosed his sexual interest in or contact with men to anyone. This patient did not suffer from hyposexual desire disorder. His problems arose from conflicted feelings about his sexual orientation.

A 44-year-old married man had a history of good sexual interaction with his wife of 18 years until 8 months prior to his consultation. Nine months ago, he had sought help for a depression triggered by the loss of employment, financial stress, and lack of immediate prospects for a new job. He had become lethargic and withdrawn and was doing little to pursue new work. He was treated with fluoxetine, 20 mg per day, which helped him, and currently, he was actively networking in pursuit of employment. However, his sexual interest remained diminished. His diminished libido appeared to be a side effect of his medication, and his diagnosis was pharmacologically induced hyposexual desire disorder.

Female Sexual Interest/Arousal Disorder

The combination of interest (or desire) and arousal into one dysfunction category reflects the recognition that women do not necessarily move stepwise from desire to arousal but often experience desire synchronously with or even following beginning feelings of arousal. This is particularly true for women in long-term relationships. As a corollary, women experiencing sexual dysfunction may experience either/or both inability to feel interest or arousal, and they may often have difficulty achieving orgasm or experience pain in addition. Some may experience dysfunction across the entire range of sexual response/pleasure. Complaints in this dysfunction category present variously as a decrease or paucity of erotic feelings, thoughts, or fantasies; a decreased impulse to initiate sex; a decreased or absent receptivity to partner overtures; or an inability to respond to partner stimulation (Table 21.1–6).

A complicating factor in this diagnosis is that a subjective sense of arousal is often poorly correlated with genital lubrication in both normal and dysfunctional women. Therefore, complaints of lack of pleasure are sufficient for these diagnoses even when vaginal lubrication and congestion are present. A woman complaining of lack of arousal may lubricate vaginally but may not experience a subjective sense of excitement. Some studies using functional magnetic resonance imaging (fMRI) have revealed a low correlation between brain activation in areas controlling genital response and simultaneous ratings of subjective arousal. Physiologic studies of sexual dysfunctions indicate that a hormonal pattern may contribute to responsiveness in women who have arousal dysfunction. Masters and Johnson found that women are particularly desirous of sex before the onset of the menses. Other women report feeling the greatest sexual excitement immediately after the menses or at the time of ovulation. Alterations in testosterone, estrogen, prolactin, and thyroxin levels have been implicated in female sexual arousal disorder. In addition, medication with antihistaminic or anticholinergic properties causes a decrease in vaginal lubrication.

Table 21.1–6.

DSM-5 Diagnostic Criteria for Female Sexual Interest/Arousal Disorder

A. Lack of, or significantly reduced, sexual interest/arousal, as manifested by at least three of the following:
    1. Absent/reduced interest in sexual activity.
    2. Absent/reduced sexual/erotic thoughts or fantasies.
    3. No/reduced initiation of sexual activity, and typically unreceptive to a partner's attempts to initiate.
    4. Absent/reduced sexual excitement/pleasure during sexual activity in almost all or all (approximately 75–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).
    5. Absent/reduced sexual interest/arousal in response to any internal or external sexual/erotic cues (e.g., written, verbal, visual).
    6. Absent/reduced genital or nongenital sensations during sexual activity in almost all or all (approximately 75–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).

B. The symptoms in criterion A have persisted for a minimum duration of approximately 6 months.

C. The symptoms in criterion A cause clinically significant distress in the individual.

D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress (e.g., partner violence) or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify whether:

Lifelong: The disturbance has been present since the individual became sexually active.

Acquired: The disturbance began after a period of relatively normal sexual function.

Specify whether:

Generalized: Not limited to certain types of stimulation, situations, or partners.

Situational: Only occurs with certain types of stimulation, situations, or partners.

Specify current severity:

Mild: Evidence of mild distress over the symptoms in criterion A.

Moderate: Evidence of moderate distress over the symptoms in criterion A.

Severe: Evidence of severe or extreme distress over the symptoms in criterion A.

Factors such as life stresses, menopause, presence of adequate sexual stimulation must be evaluated before making this diagnosis. Relationship problems are particularly relevant to acquired interest/arousal disorder. In one study of couples with markedly decreased sexual interaction, the most prevalent etiology was marital discord.

A couple presented for therapy, stating that they had not had sexual relations for 3 years. The man was aged 56 years, and the woman was 54. They had been married for 21 years and reported that their relationship was gratifying aside from the lack of sex which bothered both of them. Although they had sexual relations in the past, those interactions had been troublesome to each party. The man suffered from premature ejaculation, about which he was ashamed.

The woman complained of being frustrated with their sexual activity. In addition, she experienced his dysfunction as a personal rejection and a sign of lack of sufficient love for and consideration of her. Although she still experienced desire in the form of fantasies, her receptivity to sexual intimacy with him disappeared. She began rejecting him if he initiated sex, resulting in the cessation of any sexual interaction between them.

In addition to his early ejaculation, the couple was dealing with her acquired sexual interest/arousal disorder.

Male Erectile Disorder

The male erectile disorder was historically called *impotence.* The term was dropped for a more medical designation but also because it was considered derogatory and had negative connotations for the man affected with the problem. However, it describes with accuracy the feelings of powerlessness, helplessness, and resultant low self-esteem men with this dysfunction frequently suffer (Table 21.1–7). A man with a lifelong male erectile disorder has never been able to obtain an erection sufficient for insertion. In acquired male erectile disorder, a man has successfully achieved penetration at some time in his sexual life but is later unable to do so. In situational male erectile disorder, a man is able to have coitus in certain circumstances but not in others; for example, he may function effectively with a prostitute but be unable to have an erection when with his partner. Erectile disorder is also diagnosed when the man can obtain an erection but cannot maintain it for a reasonable amount of time necessary to complete the sex act.

Table 21.1–7.
DSM-5 Diagnostic Criteria for Male Erectile Disorder

A. At least one of the three following symptoms must be experienced on almost all or all (approximately 75–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
   1. Marked difficulty in obtaining an erection during sexual activity.
   2. Marked difficulty in maintaining an erection until the completion of sexual activity.
   3. Marked decrease in erectile rigidity.

B. The symptoms in criterion A have persisted for a minimum duration of approximately 6 months.

C. The symptoms in criterion A cause clinically significant distress in the individual.

D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify whether:

Lifelong: The disturbance has been present since the individual became sexually active.

Acquired: The disturbance began after a period of relatively normal sexual function.

Specify whether:

Generalized: Not limited to certain types of stimulation, situations, or partners.

Situational: Only occurs with certain types of stimulation, situations, or partners.

Specify current severity:

Mild: Evidence of mild distress over the symptoms in criterion A.

Moderate: Evidence of moderate distress over the symptoms in criterion A.

Severe: Evidence of severe or extreme distress over the symptoms in criterion A.

Acquired male erectile disorder has been reported in 10% to 20% of all men. Freud declared it common among his patients. Erectile disorder is the chief complaint of more than 50% of all men treated for sexual disorders. Lifelong male erectile disorder is rare; it occurs in about 1% of men under age 35. The incidence of erectile disorder increases with age. It has been reported variously as 2% to 8% of the young adult population. Alfred Kinsey reported that 75% of all men were impotent at age 80. There is a reported incidence of 40% to 50% in men between ages 60 and 70. All men over 40, Masters and Johnson claimed, have a fear of impotence, which the researchers believed reflected the masculine fear of loss of virility with advancing age. Male erectile disorder, however, is not universal in aging men; having an available sex partner is related to continuing potency, as is a history of consistent sexual activity and the absence of vascular, neurologic, or endocrine disease. Twenty percent of men fear erectile dysfunction prior to their first coitus; the reported incidence of actual erectile dysfunction during first coitus is 8%. As Stephen Levine has stated, the first coital encounter “is a horse race between excitement and anxiety.”

Male erectile disorder can be organic or psychological or a combination of both, but in young and middle-aged men, the cause is usually psychological. A good history is of primary importance in determining the cause of the dysfunction. If a man reports having spontaneous erections at times when he does not plan to have intercourse, having morning erections, or having good erections with masturbation or with partners other than his usual one, the organic causes of his erectile disorder can be considered negligible, and costly diagnostic procedures can be avoided. Male erectile disorder caused by a general medical condition or a pharmacologic substance is discussed later in this section.

Freud ascribed one type of erectile disorder to an inability to reconcile feelings of affection toward a woman with feelings of desire for her. Men with such conflicting feelings can function only with women whom they see as degraded (*Madonna–Putana complex*). Other factors that have been cited as contributing to impotence include a punitive superego, an inability to trust, and feelings of inadequacy or a sense of being undesirable as a partner. A man may be unable to express a sexual impulse because of fear, anxiety, anger, or moral prohibition. In an ongoing relationship, the disorder may reflect difficulties between the partners, particularly when a man cannot communicate his needs or his anger in a direct and constructive way. In addition, episodes of erectile disorder are reinforcing, with the man becoming increasingly anxious before each sexual encounter.

A cohabiting man and woman, law students, aged 25 years, presented for treatment with a chief complaint of limited sexual interaction due to erectile disorder on the part of the man. He experienced morning erections and had no difficulty when he masturbated, obviating a physiologic etiology for his problem. The woman evidenced no dysfunction and appeared loving and supportive of her partner.

His history revealed normal puberty and first coitus at age 17 with a high school girlfriend to whom he was emotionally attached. Sex with her was erratic. The relationship ended when both went to different colleges, and the ending was not traumatic. Of significance in the sexual history was his description of never initiating involvements but becoming involved with girls who “chose me.” The patient was an only child and related a family history of a tyrannical father who denigrated the patient for not attending an Ivy League law school. Of note, the patient was attending a highly regarded law school, had gone to a competitive entry high school, and had attended a well-respected college. The patient was aware of having a high anxiety level. At the time of treatment, he was particularly anxious about obtaining a summer internship with a “top” law firm.

The patient’s erectile disorder was another manifestation of his general anxiety and shaky self-esteem. Behavior therapy was initiated to treat his sexual anxiety. The couple was assigned a regimen of sexual exercises designed to be minimally demanding, thus allowing the man time to gain confidence in his ability to perform sexually. With the combination of nondemand exercises and the cooperation and acceptance of his partner, the patient was able to overcome his erectile disorder.

Orgasmic Disorders

Female orgasmic disorder (also known as *inhibited female orgasm,* or *anorgasmia*) is defined as the recurrent and persistent inhibition of the female orgasm, manifested by the absence or delay of orgasm after a normal sexual excitement phase, or a marked diminution of the intensity of orgasmic sensations. Women who can achieve orgasm with noncoital clitoral stimulation but cannot experience it during coitus in the absence of manual clitoral stimulation are not categorized as anorgasmic. The woman herself reports this complaint. However, some anorgasmic women are not distressed by the lack of climax and derive pleasure from sexual activity. In the latter instance, a woman may present with this complaint because her partner is troubled by her lack of orgasm.

Physiologic research on the female sexual response has demonstrated that orgasms caused by clitoral stimulation are physiologically identical to those caused by vaginal stimulation. Freud's theory that women must give up clitoral sensitivity for vaginal sensitivity to achieve sexual maturity is now considered misleading, although some women say that they gain a special sense of satisfaction from an orgasm precipitated by coitus. Some therapists attribute that to the psychological feeling of closeness engendered by the act of coitus, but others maintain that the coital orgasm is a physiologically different experience. Many women achieve orgasm during coitus by a combination of manual clitoral stimulation and penile–vaginal stimulation.

A woman with a lifelong female orgasmic disorder has never experienced orgasm by any kind of stimulation. A woman with an acquired orgasmic disorder has previously experienced at least one orgasm, regardless of the circumstances or means of stimulation, whether by masturbation or while dreaming during sleep. Studies have shown that women achieve orgasm more consistently with masturbation than with partnered sex. Kinsey found that 5% of married women over 35 years of age had never achieved orgasm by any means. The incidence of never having experienced orgasm is reported as 10% among all women. The incidence of orgasm increases with age. According to Kinsey, the first orgasm occurs during adolescence in about 50% of women as a result of masturbation or genital caressing with a partner; the rest usually experience orgasm as they get older. Lifelong female orgasmic disorder is more common among unmarried women than married women. Increased orgasmic potential in women over 35 years of age has been explained on the basis of less psychological inhibition, greater sexual experience, or both.

Acquired female orgasmic disorder is a common complaint in clinical populations. One clinical treatment facility reported having about four times as many nonorgasmic women in its practice as female patients with all other sexual disorders. In another study, 46% of women complained of difficulty reaching orgasm. Inhibition of arousal and orgasmic problems often occur together. The overall prevalence of female orgasmic disorder from all causes is estimated to be 30%. A recent twin study suggests that orgasmic dysfunction in some females has a genetic basis and cannot be attributed solely to cultural differences or developmental experiences. In that study population researchers found an estimated heritability for difficulty reaching orgasm with intercourse of 34% (similar to the population at large) and an estimated heritability for difficulty reaching orgasm with masturbation of 45% (a considerably greater percentage than the population at large).

Numerous psychological factors are associated with female orgasmic disorder. They include fears of impregnation, rejection by a sex partner, and damage to the vagina; hostility toward men; poor body image, and feelings of guilt about sexual impulses. Some women equate orgasm with loss of control or with aggressive, destructive, or violent impulses; their fear of these impulses may be expressed through inhibition of arousal or orgasm.

Prolonged marital discord may lead to acquired anorgasmia. Cultural expectations and social restrictions on women are also relevant. Many women have grown up to believe that sexual pleasure is not a natural entitlement for the so-called decent women. Nonorgasmic women may be otherwise symptom free or may experience frustration in a variety of ways; they may have such pelvic complaints as lower abdominal pain, itching, and vaginal discharge, as well as increased tension, irritability, and fatigue.

A 36-year-old woman presented with extreme distress over being anorgasmic. She was unmarried and had recently ended a relationship in which she had been very attracted to the man but was embarrassed by her lack of orgasm, about which she never told him. The patient could not bring herself to orgasm by masturbation and was reluctant to fantasize.

As a child, she had witnessed the primal scene three times that she could remember. Her parents made no attempt to close their door while having sex, and she found herself listening for sounds of coitus.

Treatment focused both on masturbatory exercises with encouragement to fantasize and material to stimulate fantasy and analytically oriented psychotherapy to deal with oedipal conflicts and inappropriate sexual stimulation during childhood.

Delayed Ejaculation

In male delayed ejaculation, sometimes called *retarded ejaculation,* a man achieves ejaculation during coitus with great difficulty, if at all. The problem is sometimes present with masturbation but appears as a problem primarily during partnered sex. A man with lifelong delayed ejaculation has never been able to ejaculate during partnered sexual activity. The problem is usually most pronounced during coital activity. The disorder is diagnosed as acquired if it develops after previously normal functioning. Some researchers think that orgasm and ejaculation should be differentiated, especially in the case of men who ejaculate but complain of a decreased or absent subjective sense of pleasure during the orgasmic experience (orgasmic anhedonia).

The incidence of male orgasmic disorder is much lower than the incidence of premature ejaculation or erectile disorder. Masters and Johnson reported an incidence of delayed ejaculation of only 3.8% in one group of 447 men with sexual dysfunctions. A general prevalence of 5% has been reported. However, an increase in the presentation of this disorder in sex therapy programs has been seen in the more recent past. This has been attributed to the increasing use of antidepressants which can have a side effect of delayed ejaculation and high use of internet pornography sites. These sites offer a level of stimulation involving such a variety of people and acts that they may inure the man to the stimulation of more typical partnered activity. One study of adolescent males who used these sites frequently, prior to live sexual interaction, reported that these teens do not develop neuronal synapses that will enable them to respond to usual partnered interactions with sufficient pleasure to allow them to achieve climax.

Lifelong delayed ejaculation indicates severe psychopathology. A man may come from a rigid, puritanical background; he may perceive sex as sinful and the genitals as dirty, and he may have conscious or unconscious incest wishes and guilt. He usually has difficulty with closeness in areas beyond those of sexual relations. In a few cases, the condition is aggravated by an attention deficit disorder. A man's distractibility prevents sufficient arousal for a climax to occur.

In an ongoing relationship, acquired male delayed ejaculation disorder frequently reflects interpersonal difficulties. The disorder may be a man's way of coping with real or fantasized changes in a relationship, such as plans for pregnancy about which the man is ambivalent, the loss of sexual attraction to the partner, or demands by the partner for greater commitment as expressed by sexual performance. In some men, the inability to ejaculate reflects unexpressed hostility toward a woman. The problem is more common among men with obsessive-compulsive disorder (OCD) than among others.

A 43-year-old married man presented with delayed ejaculation of 5 months duration. The onset of the dysfunction coincided with his agreeing to try to have a child with his wife. This was the patient's second marriage, and he had a 9-year-old daughter from his first marriage who lived primarily with his ex-wife. He and his current wife had discussed having children before they married. Although the patient did not want another child, he agreed to father one because his current wife, age 39, was childless, and he felt it would be selfish to deny her a baby. He was afraid of losing his wife if they did not try to conceive. Therapy involved behavioral exercises geared to restore the patient's pleasure in sexuality as well as introspective psychotherapy to address his ambivalence about conception.

A 31-year-old male presented with a history of lifelong delayed ejaculation intravaginally. He was engaged to be married, and his fiancée was increasingly distressed by his dysfunction. The patient demonstrated obsessive characteristics. For example, he refused to allow his fiancée to hang up his shirts because he was adamant that they be spaced apart to an exact degree. In addition, he had been traumatized in his adolescence by seeing his mother miscarry a pregnancy “all over the kitchen floor.” The couple was treated with behavioral sex therapy exercises.

Delayed ejaculation may have physiologic causes and can occur after surgery of the genitourinary tract, for example, with a prostatectomy. Delayed ejaculation may also be associated with Parkinson disease and other neurologic disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drugs guanethidine monosulfate (Ismelin) and methyldopa (Aldomet) have been implicated in delayed ejaculation, as have the phenothiazines and almost all the antidepressants. Strictly organic cases are diagnosed as medically or pharmacologically induced sexual dysfunction.

Early Ejaculation

In early ejaculation, men persistently or recurrently achieve orgasm and ejaculation before they wish to. The diagnosis is made when a man regularly ejaculates before or within approximately 1 minute after penetration. DSM-5 refers only to “vaginal penetration” in its diagnostic criteria even though it is entirely possible for the disorder to occur in men who are homosexual and do not engage in vaginal penetration. DSM-5 defines the disorder as mild if ejaculation occurs within approximately 30 seconds to 1 minute of vaginal penetration, moderate if ejaculation occurs within approximately 15 to 30 seconds of vaginal penetration, and severe when ejaculation occurs at the start of sexual activity or within approximately 15 seconds of vaginal penetration. A difficulty with these specifiers involves time distortions which patients make in both overestimating and underestimating time from penetration to climax. Clinicians need to consider factors that affect the duration of the excitement phase of the sexual response, such as age, the novelty of the sex partner, and the frequency and duration of coitus. As with the other sexual dysfunctions, premature ejaculation is not diagnosed when it is caused exclusively by organic factors or when it is symptomatic of another clinical psychiatric syndrome.

Early ejaculation is more commonly reported among college-educated men than among men with less education. The complaint is thought to be related to their concern for partner satisfaction, but the true cause of this increased frequency has not been determined. Early ejaculation is the chief complaint of about 35% to 40% of men treated for sexual disorders. In DSM-5, the writers state that the disorder, with its newly defined time parameter, would now be an accurate diagnosis for only 1% to 3% of men. Some researchers divide men who experience early ejaculation into two groups: those who are physiologically predisposed to climax quickly because of shorter nerve latency time and those with a psychogenic or behaviorally conditioned cause. Difficulty in ejaculatory control can be associated with anxiety regarding the sex act, with unconscious fears about the vagina, or with negative cultural conditioning. Men whose early sexual contacts occurred largely with prostitutes who encourage a rapid conclusion of the sex act, or whose sexual contacts took place in situations in which discovery would be embarrassing (e.g., in a shared dormitory room or in the parental home) might have been conditioned to achieve orgasm rapidly. With young, inexperienced men, who have the problem, it may resolve in time. In ongoing relationships, the partner has a great influence on a premature ejaculator, and a stressful marriage exacerbates the disorder. The developmental background and the psychodynamics found in premature ejaculation and in erectile disorder are similar.

PAIN DISORDER

Genitopelvic Pain/Penetration Disorder

In DSM-5, this disorder refers to one or more of the following complaints, of which any two or more may occur together: difficulty having intercourse; genitopelvic pain; fear of pain or penetration; and tension of the pelvic floor muscles. Previously, these pain disorders were diagnosed as *dyspareunia* or *vaginismus.* These former diagnoses could coexist with each other or lead to one another and could understandably lead to fear of pain with sex. Thus, it is reasonable to gather them into one diagnostic category. For purposes of clinical discussion, however, the distinct categories of dyspareunia and vaginismus remain useful.

Dyspareunia. Dyspareunia is recurrent or persistent genital pain occurring before, during, or after intercourse. Dyspareunia is related to and often coincides with vaginismus. Repeated episodes of vaginismus can lead to dyspareunia and vice versa; in either case, somatic causes must be ruled out. DSM-5 cites that 15% of women in North America report recurrent pain during intercourse.

In most cases, dynamic factors are considered causative. Chronic pelvic pain is a common complaint in women with a history of rape or childhood sexual abuse. Painful coitus can result from tension and anxiety about the sex act that causes women to involuntarily contract their pelvic floor muscles. The pain is real and makes intercourse unpleasant or unbearable. Anticipation of further pain may cause women to avoid coitus altogether. If a partner proceeds with intercourse regardless of a woman's state of readiness, the condition is aggravated. There is an increase in reported dyspareunia postmenopausally due to hormonally induced physiologic changes in the vagina; however, specific complaints of difficulty having intercourse occur more often in premenopausal women. There is some increase in dyspareunia in the immediate postpartum population, but it is usually temporary. Dyspareunia may present as any of the four complaints listed under genitopelvic pain/penetration disorder and should be diagnosed as genitopelvic pain/penetration disorder.

A 20-year-old woman presented with pelvic pain/penetration disorder 6 months after her marriage. She and her husband had experienced manual sex play to which she responded with some arousal, but the marriage remained unconsummated. The woman had been brought up in an orthodox Jewish community, where virginity was an imperative and social and sexual interaction between adolescent and young adult men and women were limited. The patient had minimal experience dating, and her husband was similarly inexperienced sexually. Therapy consisted of sex education and behavioral sexual exercises.

Dyspareunia can occur in men, but it is uncommon and usually associated with a medical condition such as Peyronie disease, prostatitis, or gonorrheal or herpetic infections. Vasocongestion during sexual activity without orgasmic release also may lead to discomfort. Rarely, some men experience pain during ejaculation (postejaculatory pain disorder). This pain is caused by an involuntary spasm of the perineal muscles that may be due to psychological conflicts about the sex act or may be an adverse effect of some antidepressant medications. Sexual dysfunction caused by medication is the diagnosis used when a substance or medication is the sole or major causal factor for the pain.

Sexual Dysfunction Due to a General Medical Condition

The category of sexual dysfunction due to a general medical condition covers sexual dysfunction that results in marked distress and interpersonal difficulty when there is evidence from the history, physical examination, or laboratory findings of a general medical condition judged to be causally related to the sexual dysfunction.

Male Erectile Disorder Due to a General Medical Condition. Many studies have focused on the relative incidences of psychological and organic male erectile disorder. Statistics indicate that 20% to 50% of men with erectile disorder have an organic basis for the disorder. A physiologic etiology is more likely in men older than 50 and the most likely cause in men older than age 60. Physiologically, erectile dysfunction may be due to a variety of medical causes (Table 21.1–8). In the United States, it is estimated that two million men cannot gain erections because they suffer from diabetes mellitus; an additional 300,000 are dysfunctional because of other endocrine diseases; approximately 1.5 million are dysfunctional as a result of vascular disease; an estimated 180,000 because of multiple sclerosis; approximately 400,000 because of traumas and fractures leading to pelvic fractures or spinal cord injuries; and another 650,000 are estimated to be dysfunctional as a result of radical surgery, including prostatectomies, colostomies, and cystectomies. In addition, the clinician should be aware of the possible pharmacologic effects of medication on sexual functioning. The increased incidence of organic causes for erectile dysfunction may partly reflect the increased use of psychotropic and antihypertensive medications. Adverse effects of medication may impair male sexual functioning in a variety of ways. Castration (removal of the testes) does not always lead to sexual dysfunction, depending on the person. Erection may still occur after castration via a reflex arc that passes through the sacral cord erectile center. It is triggered when the inner thigh is stimulated.

Table 21.1–8.
Diseases and Other Medical Conditions Implicated in Erectile Dysfunction

- Infectious and parasitic diseases
    - Elephantiasis
    - Mumps
- Cardiovascular disease
    - Atherosclerotic disease
    - Aortic aneurysm
    - Leriche syndrome
    - Cardiac failure
- Renal and urologic disorders
    - Peyronie disease
    - Chronic renal failure
    - Hydrocele and varicocele
- Hepatic disorders
    - Cirrhosis (usually associated with alcohol dependence)
- Pulmonary disorders
    - Respiratory failure
- Genetic disorders
    - Klinefelter syndrome
    - Congenital penile vascular and structural abnormalities
- Nutritional disorders
    - Malnutrition
    - Vitamin deficiencies
- Endocrine disorders
    - Diabetes mellitus
    - Dysfunction of the pituitary–adrenal–testis axis
    - Acromegaly
    - Addison disease
    - Chromophobe adenoma
    - Adrenal neoplasia
    - Myxedema
    - Hyperthyroidism
- Neurologic disorders
    - Multiple sclerosis
    - Transverse myelitis
    - Parkinson disease
    - Temporal lobe epilepsy
    - Traumatic and neoplastic spinal cord diseases

  - Central nervous system tumor
  - Amyotrophic lateral sclerosis
  - Peripheral neuropathy
  - General paresis
  - Tabes dorsalis
- Pharmacologic contributants
  - Alcohol, tobacco, and other dependence-inducing substances (heroin, methadone, morphine, cocaine, amphetamines, and barbiturates)
  - Prescribed drugs (psychotropic drugs, antihypertensive drugs, estrogens, and antiandrogens)
- Poisoning
  - Lead (plumbism)
  - Herbicides
- Surgical procedures
  - Perineal prostatectomy
  - Abdominal–perineal colon resection
  - Sympathectomy (frequently interferes with ejaculation)
  - Aortoiliac surgery
  - Radical cystectomy
  - Retroperitoneal lymphadenectomy
- Miscellaneous
  - Radiation therapy
  - Pelvic fracture
  - Any severe systemic disease or debilitating condition

The mechanisms involved in the various diseases that lead to erectile disorder include general endothelial dysfunction or dysfunction of the penile endothelium specifically, atherosclerosis, dysregulation of nitric oxide synthase, a decrease of nitric oxide, low testosterone levels due to hyperprolactinemia-influenced changes in the hypothalamic–pituitary axis, vasculopathy, autonomic neuropathy, and disruption of neural proerectile processes.

PHYSIOLOGIC TESTS. A number of procedures, benign and invasive, are used to help differentiate psychogenic erectile dysfunction. The procedures include monitoring nocturnal penile tumescence (erection that occurs during sleep) normally associated with rapid eye movement; monitoring tumescence with a strain gauge; measuring blood pressure in the penis with a penile plethysmograph or an ultrasound (Doppler) flow meter, both of which assess blood flow in the internal pudendal artery; and measuring pudendal nerve latency time. Neurologic impairment of penile function may be indicated by a decreased vibratory perception in the penis. Other diagnostic tests that delineate organic bases for erectile disorder include glucose tolerance tests, plasma hormone assays, liver and thyroid function tests, prolactin and follicle-stimulating hormone (FSH) determinations, and cystometric examinations. On physical examination, evidence of hypogonadism such as small testes, gynecomastia, reduced or absent body, and facial hair warrant attention. Invasive diagnostic studies include penile arteriography, infusion cavernosonography, and radioactive xenon penography. Invasive procedures require expert interpretation and are used only for patients who are candidates for vascular reconstructive procedures.

MEDICAL VERSUS PSYCHOGENIC CAUSES. A good history is crucial to determining the cause of the male erectile disorder. If a man reports having spontaneous erections at times when he does not plan to have intercourse, having morning erections or only sporadic erectile dysfunction, or having good erections with masturbation or with partners other than his usual one, then organic causes for his disorder can be considered negligible, and costly diagnostic procedures can be avoided. When a medical basis for erectile dysfunction is found, psychological factors often contribute to the dysfunction, and psychiatric treatment may be helpful. Some diabetics, for instance, may experience psychogenic erectile dysfunction.

Dyspareunia Due to a General Medical Condition. An estimated 30% of all surgical procedures on the female genital area result in temporary dyspareunia. In addition, 30% to 40% of women with the complaint who are seen in sex therapy clinics have pelvic pathology. Organic abnormalities leading to dyspareunia and vaginismus include infected hymenal remnants or congenitally imperforate or unusually thick hymens; episiotomy scars; Bartholin glands infections; various forms of vaginitis and cervicitis; testosterone deficiency; vulvodynia; vaginal treatment, such as radiation or surgery that has caused scarring; dermatologic disorder, such as lichens sclerosis or lichens planus; and endometriosis. Postcoital pain reported by women with myomata and endometriosis is attributed to uterine contractions during orgasm. Postmenopausal women may have dyspareunia because of thinning of the vaginal mucosa and reduced lubrication. Women who have been on birth control pills for many years may have lessened lubrication and mild vaginal thinning similar to the postmenopausal woman.

Dyspareunia can also occur in men, but it is uncommon and is usually associated with an organic condition such as Peyronie disease, which consists of sclerotic plaques on the penis that cause penile curvature and make penetration difficult and painful.

Hypoactive Sexual Desire and Arousal/Interest Disorder Due to a General Medical Condition. Desire commonly decreases after major illness or surgery, particularly when body image is affected after such procedures as mastectomy, ileostomy, hysterectomy, and prostatectomy. Illnesses that deplete a person's energy, chronic conditions that require physical and psychological adaptation, and serious illnesses that may cause the person to become depressed can all result in a marked lessening of sexual desire or interest in both men and women. In some cases, biochemical correlates are associated with hypoactive sexual desire disorder (Table 21.1–9). A recent study found markedly lower serum testosterone concentrations in men complaining of low desire than in normal controls in a sleep laboratory situation. Drugs that depress the central nervous system (CNS) or decrease testosterone production can decrease desire.

Table 21.1–9.
Neurotransmitter Effects on Sex Function

	Dopamine	Serotonin	Adrenergic	Cholinergic	Clinical Correlation
Erection	++	+/–	α, β – +	+/–	Antipsychotics (dopamine receptor antagonists) may lead to erectile dysfunction; dopaminergic drug agonists may lead to enhanced erection and libido; priapism with trazodone (α_1 block); β-adrenergic receptor antagonists may lead to impotence.
Ejaculation and orgasm	+/–	+	+α_1	+/–	α_1-Adrenergic receptor antagonists, tricyclic drugs, MAOIs, thioridazine may lead to impaired ejaculation; serotonergic agents may inhibit orgasm.

+/–, minimal or no effect; +, facilitates effect; –, inhibiting effect; MAOI, monoamine oxidase inhibitor.

Other Male Sexual Dysfunction Due to a General Medical Condition

Delayed ejaculation can have physiologic causes and can occur after surgery on the genitourinary tract, such as prostatectomy. It may also be associated with Parkinson disease and other neurologic disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drug guanethidine monosulfate (Ismelin), methyldopa (Aldomet), the phenothiazines, the tricyclic drugs, and the selective serotonin reuptake inhibitors (SSRIs), among others, have been implicated in retarded ejaculation. Delayed ejaculation must also be differentiated from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes back into the bladder. Retrograde ejaculation always has an organic cause. It can develop after genitourinary surgery and is also associated with medications that have anticholinergic adverse effects, such as some phenothiazines.

Other Female Sexual Dysfunction Due to a General Medical Condition

Some medical conditions—specifically endocrine diseases such as hypothyroidism, diabetes mellitus, and primary hyperprolactinemia—can affect a woman's ability to have orgasms. Several drugs also affect some women's capacity to have orgasms. Antihypertensive medications, tricyclic drugs, SSRIs, and, frequently, monoamine oxidase inhibitors (MAOIs) have interfered with female orgasmic capacity. One study of women taking MAOIs, however, found that after 16 to 18 weeks of pharmacotherapy, the adverse effect of the medication disappeared, and the women were able to reexperience orgasms, although they continued taking an undiminished dosage of the drug.

SUBSTANCE/MEDICATION-INDUCED SEXUAL DYSFUNCTION

The diagnosis of substance-induced sexual dysfunction is used when evidence of substance intoxication or withdrawal is apparent from the history, physical examination, or laboratory findings. The disturbance in sexual function must be predominant in the clinical picture. Distressing sexual dysfunction occurs soon after significant substance intoxication or withdrawal or after exposure to a medication or a change in medication use. Specified substances include alcohol, amphetamines, or related substances, cocaine, opioids, sedatives, hypnotics, or anxiolytics, and other or unknown substances.

Abused recreational substances affect sexual function in various ways. In small doses, many substances enhance sexual performance by decreasing inhibition or anxiety or by causing a temporary elation of mood. With continued use, however, erectile engorgement and orgasmic and ejaculatory capacities become impaired. The abuse of sedatives, anxiolytics, hypnotics, and particularly opiates and opioids nearly always depresses desire. Alcohol may foster the initiation of sexual activity by removing inhibition, but it also impairs performance. Cocaine and amphetamines produce the following similar effects: although no direct evidence indicates that sexual drive is enhanced, users initially have feelings of increased energy and may become sexually active; ultimately, dysfunction occurs. Men usually go through two stages: an experience of prolonged erection without ejaculation, then a gradual loss of erectile capability.

Patients recovering from substance dependency may need therapy to regain sexual function, partly because of psychological readjustment to a nondependent state. Many substance abusers have always had difficulty with intimate interactions. Others who spent their crucial developmental years under the influence of a substance have missed the experiences that would have enabled them to learn social and sexual skills.

Pharmacologic Agents Implicated in Sex Dysfunction

Almost every pharmacologic agent, particularly those used in psychiatry, has been associated with an effect on sexuality. In men, these effects include decreased sex drive, erectile failure, decreased volume of ejaculate, and delayed or retrograde ejaculation. In women, decreased sex drive, decreased vaginal lubrication, inhibited or delayed orgasm, and decreased or absent vaginal contractions may occur. Drugs may also enhance the sexual responses and increase the sex drive, but this is less common than adverse effects. The effects of psychoactive drugs are detailed below.

Antipsychotic Drugs. Most antipsychotic drugs are dopamine receptor antagonists that also block adrenergic and cholinergic receptors, thus accounting for adverse sexual effects (see Table 21.1–9). Chlorpromazine (Thorazine) and trifluoperazine (Stelazine) are potent anticholinergics, and they impair erection and ejaculation. With some drugs, the seminal fluid backs up into the bladder rather than being propelled through the penile urethra. Patients still have a pleasurable sensation, but the orgasm is dry. When urinating after orgasm, the urine may be milky white because it contains the ejaculate. The condition is startling but harmless. Paradoxically, some rare cases of priapism have been reported with antipsychotics.

Antidepressant Drugs. The tricyclic and tetracyclic antidepressants have anticholinergic effects that interfere with erection and delay ejaculation. Because the anticholinergic effects vary among the cyclic antidepressants, those with the fewest effects (e.g., desipramine [Norpramin]) produce the fewest sexual adverse effects. The effects of the tricyclics and tetracyclics have not been documented sufficiently in women; however, few women seem to complain of any effects.

Some men report increased sensitivity of the glans that is pleasurable, and that does not interfere with erection, although it delays ejaculation. In some cases, however, the tricyclic causes painful ejaculation, perhaps as the result of interference with seminal propulsion caused by interference with, in turn, urethral, prostatic, vas, and epididymal smooth muscle contractions. Clomipramine (Anafranil) has been reported to increase sex drive in some persons. Selegiline (Deprenyl), a selective MAO type B (MAO_B) inhibitor, and bupropion (Wellbutrin) have also been reported to increase sex drive, possibly by dopaminergic activity and increased production of norepinephrine.

Venlafaxine (Effexor) and SSRIs most often have adverse effects because of the rise in serotonin levels. A lowering of the sex drive and difficulty reaching orgasm occur in both sexes. Reversal of those negative effects has been achieved with cyproheptadine (Periactin), an antihistamine with antiserotonergic effects, and with methylphenidate (Ritalin), which has adrenergic effects. Trazodone (Desyrel) is associated with the rare occurrence of priapism, the symptom of prolonged erection in the absence of sexual stimuli. That symptom appears to result from the α_2-adrenergic antagonism of trazodone.

The MAOIs affect biogenic amines broadly. Accordingly, they produce impaired erection, delayed or retrograde ejaculation, vaginal dryness, and inhibited orgasm. Tranylcypromine (Parnate) has a paradoxical sexually stimulating effect in some persons, possibly as a result of its amphetamine-like properties.

General Effects. Because depression is associated with a decreased libido, varying levels of sexual dysfunction and anhedonia are part of the disease process. Some patients report improved sexual functioning as their depression improves as a result of antidepressant medication. The phenomenon makes the evaluation of sexual side effects difficult; also, the side effects may disappear with time, perhaps because a biogenic amine homeostatic mechanism comes into play.

LITHIUM. Lithium (Eskalith) regulates mood and, in the manic state, may reduce hypersexuality, possibly by a dopamine antagonist activity. In some patients, impaired erection has been reported.

SYMPATHOMIMETICS. Psychostimulants, which are sometimes used in the treatment of depression, include amphetamines, methylphenidate, and pemoline (Cylert), which raise the plasma levels of norepinephrine and dopamine. Libido is increased; however, with prolonged use, men may experience a loss of desire and erections.

α-ADRENERGIC AND β-ADRENERGIC RECEPTOR ANTAGONISTS. α-Adrenergic and β-adrenergic receptor antagonists are used in the treatment of hypertension, angina, and certain cardiac arrhythmias. They diminish tonic sympathetic nerve outflow from vasomotor centers in the brain. As a result, they can cause impotence, decrease the volume of ejaculate, and produce retrograde ejaculation. Changes in libido have been reported in both sexes.

Suggestions have been made to use the side effects of drugs therapeutically. Thus, a drug that delays or interferes with ejaculation (e.g., fluoxetine [Prozac]) might be used to treat premature ejaculation.

ANTICHOLINERGICS. Anticholinergics block cholinergic receptors and include such drugs as amantadine (Symmetrel) and benztropine (Cogentin). They produce dryness of the mucous membranes (including those of the vagina) and erectile disorder. However, amantadine may reverse SSRI-induced orgasmic dysfunction through its dopaminergic effect.

ANTIHISTAMINES. Drugs such as diphenhydramine (Benadryl) have anticholinergic activity and are mildly hypnotic. They may inhibit sexual function as a result. Cyproheptadine, although an antihistamine, also has potent activity as a serotonin antagonist. It is used to block the serotonergic sexual adverse effects produced by SSRIs, such as delayed orgasm.

ANTIANXIETY AGENTS. The major class of anxiolytics is the benzodiazepines (e.g., diazepam [Valium]). They act on the γ-aminobutyric acid (GABA) receptors, which are believed to be involved in cognition, memory, and motor control. Because they decrease plasma epinephrine concentrations, they diminish anxiety, and as a result, they improve sexual function in persons inhibited by anxiety.

ALCOHOL. Alcohol suppresses CNS activity generally and can produce erectile disorders in men as a result. Alcohol has a direct gonadal effect that decreases testosterone levels in men; paradoxically, it can produce a slight rise in testosterone levels in women. The latter finding may account for women reporting increased libido after drinking small amounts of alcohol. The long-term use of alcohol reduces the ability of the liver to metabolize estrogenic compounds. In men, that produces signs of feminization (such as gynecomastia).

OPIOIDS. Opioids, such as heroin, have adverse sexual effects, such as erectile failure and decreased libido. The alteration of consciousness may enhance the sexual experience in occasional users.

HALLUCINOGENS. The hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), psilocybin (from some mushrooms), and mescaline (from peyote cactus). In addition to inducing hallucinations, the drugs cause a loss of contact with reality and expand a sense of consciousness. Some users report that the sexual experience is similarly enhanced, but others experience anxiety, delirium, or psychosis, which clearly interferes with sexual function.

CANNABIS. The altered state of consciousness produced by cannabis may enhance sexual pleasure for some persons. Its prolonged use depresses testosterone levels.

BARBITURATES AND SIMILARLY ACTING DRUGS. Barbiturates and similarly acting sedative–hypnotic drugs may enhance sexual responsiveness in persons who are sexually unresponsive as a result of anxiety. They have no direct effect on the sex organs; however, they do produce an alteration in consciousness that some persons find pleasurable. They are subject to abuse and can be fatal when combined with alcohol or other CNS depressants.

Methaqualone (Quaalude) acquired a reputation as a sexual enhancer, which had no biologic basis in fact. It is no longer marketed in the United States.

Other Specified Sexual Dysfunction

Diagnoses in this category include dysfunctions that distress the patient but do not meet the criteria for the disorders discussed above. An example would be sexual aversion, in which the patients cannot enjoy the sex act because of a phobic aversion to touching the genitalia.

Unspecified Sexual Dysfunction

This category covers other sexual dysfunctions that do not fall under the diagnoses discussed above but that cause distress and interference with sexual connection and pleasure. In these cases, the clinician does not choose to elaborate on the differences from the diagnoses discussed above.

Further examples of other specified or unspecified disorders include individuals who experience the physiologic components of sexual excitement and orgasm but report no erotic sensation or even anesthesia and the male experience of orgasm with a flaccid penis. The orgasmic woman who desires but has not experienced multiple orgasms can be classified under this heading as well. Disorders of excessive rather than inhibited function, such as compulsive masturbation, might be diagnosed under unspecified dysfunction. These diagnoses also might be used to cover complaints engendered by a couple, rather than individual, dysfunction—for example, a couple in which one partner prefers morning sex and the other functions more readily at night or a couple with unequal frequencies of desire.

Compulsive Sexual Behavior. The concept of compulsive sexual behavior (Table 21.1–10), or sex addiction, was developed in the 1980s to describe persons who compulsively seek out sexual experiences and whose behavior becomes impaired if they cannot gratify their sexual impulses. The concept of sex addiction is derived from the model of addiction to drugs such as heroin or addiction to behavioral patterns such as gambling. Addiction implies psychological dependence, physical dependence, and a withdrawal symptom if the substance (e.g., the drug) is unavailable or the behavior (e.g., gambling) is frustrated.

DSM-5 does not have a diagnosis of *sex addiction* or *compulsive sexual behavior*. ICD 11 includes a diagnosis of compulsive sexual behavior. A person whose entire life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but cannot do so is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience and deprivation evokes symptoms of distress. Ten-step programs are usually a necessary part of the treatment of this behavior.

Persistent Genital Arousal Disorder. Persistent genital arousal disorder has previously been called persistent sexual arousal syndrome. It has been diagnosed in women who complain of a continual feeling of sexual arousal, which is uncomfortable, demands release, and interferes with life pleasures and activities. These women frequently masturbate, sometimes incessantly, because climax provides relief. However, the relief is temporary, and the sense of arousal returns rapidly and remains. The sense of arousal in these cases is neither pleasurable nor exciting, and the women are not interested in a sexual experience but in relief from their symptoms. Some women have reported masturbating so frequently to alleviate the arousal that they have irritated their genitalia severely. One case of attempted suicide has been reported with this syndrome, with the woman stating that she could no longer tolerate the sensations and that she had masturbated so often that her vulva was raw.

Table 21.1–10.
Signs of Sexual Addiction or Compulsive Sexual Behavior

1. Out-of-control behavior
2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior
3. Persistent pursuit of self-destructive or high-risk sexual behavior
4. Repeated attempts to limit or stop sexual behavior
5. Sexual obsession and fantasy as a primary coping mechanism
6. Need for increasing amounts of sexual activity
7. Severe mood changes related to sexual activity (e.g., depression, euphoria)
8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience
9. Interference of sexual behavior in social, occupational, or recreational activities

Data from Carnes P. Don’t Call It Love. New York: Bantam Books; 1991.

Krafft-Ebing reported a case of a young woman who masturbated almost incessantly and was unable to control her impulses. She had frequent coitus with many men, but neither coitus nor masturbation sufficed, and she was eventually placed in an institution. Krafft-Ebing referred to the condition as “sexual hyperaesthesia,” which he believed could occur in otherwise normal persons.

This case would have to be differentiated from sexual addiction. The differentiating factor would be whether the woman desired an orgasm for itself and looked forward to having sex or whether she was seeking relief from incessant and intolerable stimulation. There is some speculation that this disorder is due to nerve damage or anomaly, but the etiology is unknown.

Postcoital Dysphoria. Postcoital dysphoria is not listed in DSM-5. It occurs during the resolution phase of sexual activity when individuals normally experience a sense of general well-being and muscular and psychological relaxation. Some individuals, however, experience postcoital dysphoria—after an otherwise satisfactory sexual experience, they become depressed, tense, anxious, and irritable and show psychomotor agitation. They often want to get away from their partner and may become verbally or even physically abusive. The incidence of the disorder is unknown, but it is more common in men than in women. Its several causes relate to the person's attitude toward sex in general and the partner in particular. It may occur in adulterous sex and with prostitutes, when there is a profound fear of intimacy, or when individuals cannot experience sex without consequent strong feelings of guilt. The fear of sexually transmitted infection causes some persons to experience postcoital dysphoria. Treatment requires insight-oriented psychotherapy to help patients understand the unconscious antecedents to their behavior and attitudes.

Unconsummated Marriage. A couple involved in an unconsummated marriage has never had coitus and is typically uninformed and inhibited about sexuality. Their feelings of guilt, shame, or inadequacy are increased by their problems, and they experience conflict between their need to seek help and their need to conceal their difficulty. Couples present with the problem after having been married for several months or several years. Masters and Johnson reported an unconsummated marriage of 17 years duration.

Frequently, the couple does not seek help directly, but the woman may reveal the problem to her gynecologist on a visit ostensibly concerned with vague vaginal or other somatic complaints. On examining her, the gynecologist may find an intact hymen. In some cases, however, the wife may have undergone a hymenectomy to resolve the problem. Inquiry by a physician who is comfortable in dealing with sexual problems may be the first opening to a frank discussion of the couple's distress. Often, the pretext of the medical visit is a discussion of contraceptive methods or even a request for an infertility workup. Once presented, the complaint can often be successfully treated. The duration of the problem does not significantly affect the prognosis or the outcome of the case.

The causes of unconsummated marriage are varied: lack of sex education, sexual prohibitions overly stressed by parents or society, problems of an oedipal nature, immaturity in both partners, overdependence on primary families, and problems in sexual identification. Religious orthodoxy, with severe control of sexual and social development or the equation of sexuality with sin or uncleanliness, has also been cited as a dominant cause. Many women involved in an unconsummated marriage have distorted concepts about their vaginas. They may fear that the vagina is too small or too soft, or they may confuse the vagina with the rectum, leading to feelings of being unclean. The man may share in those distortions about the vagina and, in addition, perceive it as dangerous to him. Similarly, both partners may have distortions about the man's penis, perceiving it as a weapon, as too large, or as too small. Many patients can be helped by simple education about genital anatomy and physiology, by suggestions for self-exploration, and by correct information from a physician. The problem of the unconsummated marriage is best treated by seeing both members of the couple. Dual-sex therapy has been markedly effective. However, other forms of conjoint therapy, marital counseling, traditional psychotherapy on a one-to-one basis, and counseling from a sensitive family physician, gynecologist, or urologist are all helpful.

Body Image Problems. Some individuals are ashamed of their bodies and experience feelings of inadequacy related to self-imposed standards of masculinity or femininity. They may insist on sex only during total darkness, not allow certain body parts to be seen or touched, or seek unnecessary operative procedures to deal with their perceived inadequacies. Concerns about body image occur more frequently in women than in men. Certain people have difficulty adjusting to narcissistic injuries inflicted by age or illness and withdraw from sex as a result. Body dysmorphic disorder should be ruled out.

Don Juanism. Some men who appear to be hypersexual, as shown by their need to have many sexual encounters or conquests, use their sexual activities to mask deep feelings of inferiority. Some have unconscious homosexual impulses, which they deny by compulsive sexual contact with women. After having sex, most Don Juans are no longer interested in the woman. The condition is also referred to as *satyriasis* or as a form of sex addiction.

Nymphomania. Nymphomania signifies an excessive or pathologic desire for coitus in a woman. There have been few scientific studies of the condition. Those patients who have been studied usually have had one or more sexual disorders, usually including female orgasmic disorder. The woman often has an intense fear of loss of love or a continuing need to confirm her sexual desirability. She attempts to satisfy her dependency needs rather than to gratify her sexual impulses through her actions. It is sometimes classified as a form of sex addiction.

Fantasies. Other atypical disorders are found in individuals who have one or more sexual fantasies about which they obsess, feel guilty, or are otherwise dysphoric. As indicated in Table 21.1–11, however, the range of common sexual fantasies is broad.

Postcoital Headache. Postcoital headache is a headache immediately after coitus and may last for several hours. It is usually described as throbbing and is localized in the occipital or frontal area. The cause is unknown but may be vascular, due to muscle contraction (tension), or psychogenic. Coitus may precipitate migraines or cluster headaches in predisposed persons.

Table 21.1–11.
Common Sexual Fantasies

Men	Women
Heterosexual	
Replacement of established partner	Replacement of established partner
	Forced sexual encounters with men
Forced sexual encounters with women	Observing sexual activity Idyllic encounters with unknown men
Observing sexual activity	
Sexual encounters with men	Sexual encounters with women

Orgasmic Anhedonia. Orgasmic anhedonia is a condition in which the person had no physical sensation of orgasm, even though the physiologic component (e.g., ejaculation) remains intact. Medical causes, such as sacral and cephalic lesions that interfere with afferent pathways from the genitalia to the cortex, must be ruled out. Psychological causes usually relate to extreme guilt about experiencing sexual pleasure—these feelings produce a type of dissociative response that isolates the affective component of the orgasmic experience from consciousness.

Female Premature Orgasm. Data on female premature orgasm are lacking; no separate category for premature orgasm in women is included in DSM-5. However, in one study, 10% of women felt they reached orgasm too quickly.

Masturbatory Pain. Some individuals may experience pain during masturbation. Organic causes should always be ruled out. A small vaginal tear or early Peyronie disease may produce a painful sensation. The condition should be differentiated from compulsive masturbation. People may masturbate to the extent that they do physical damage to their genitals and eventually experience pain during subsequent masturbatory acts.

Certain masturbatory practices have resulted in what has been called *autoerotic asphyxiation,* which is usually classified as a paraphilia (hypoxyphilia). The practices may involve masturbating while hanging by the neck to heighten erotic sensations and the intensity of the orgasm through the mechanism of mild hypoxia. Although they intend to release themselves from the noose after orgasm, an estimated 500 to 1,000 persons a year accidentally kill themselves by hanging. Most who indulge in the practice are men; transvestism is often associated with the habit, and most deaths occur among adolescents. Such masochistic practices are usually associated with severe mental disorders, such as schizophrenia and major mood disorders.

TREATMENT

The treatment of sexual disorders has evolved significantly since the 1970s when Masters and Johnson focused the attention of the psychiatric community on sexual disorders. Innovations in treatment reflect the results of research and changes in the patient population. For example, in the late 1960s, most cases of erectile dysfunction were considered psychological in origin, with approximately 20% of erectile problems having an organic cause. Currently, the numbers are reversed, with the majority of cases considered to result from a physiologic problem. Actually, many cases are of mixed origin. Similarly, early patients in sex therapy were assumed to suffer, in part, from lack of sexual information and culturally reinforced negative attitudes toward sex. In the past 50 years, the public has received a great deal of accurate information about sex through the media. Patients now have more knowledge and greater sexual sophistication. Their dysfunctions frequently have a complex etiology involving psychodynamic and relational issues. Problems of desire are seen with increasing frequency and are among the most challenging cases for therapists. Couples' issues involve problems of trust, intimacy, lack of sexual attraction, and struggles for dominance. Finally, along with the rest of psychiatry, sex therapy has experienced medicalization. Biologic treatment approaches have developed rapidly. An eclectic approach that allows the use of several techniques sequentially or in combination may be necessary.

Before entering therapy, the patient may need a thorough medical evaluation, including medical history, physical examination, and appropriate laboratory studies when necessary. If a medical cause for the disorder is found, treatment should be directed toward ameliorating that cause.

Before 1970, the most common treatment of sexual dysfunction was individual psychotherapy. Classic psychodynamic theory considers sexual inadequacy to have its roots in early developmental conflicts, and the sexual disorder is treated as part of a more pervasive emotional disturbance. Treatment focuses on the exploration of unconscious conflicts, motivation, fantasy, and various interpersonal difficulties. Therapy assumes that removal of the conflicts will allow the sexual impulse to become structurally acceptable to the patient's ego and thereby find appropriate means of satisfaction in the environment. Unfortunately, the symptom of sexual dysfunction frequently becomes secondarily autonomous and persists after the resolution of the other problems evolving from the patient's pathology. The addition of behavioral techniques is often necessary to cure the sexual problem.

Dual-Sex Therapy

The theoretical basis of the dual-sex therapy approach is the concept of the marital unit or dyad as the object of therapy. The method of dual-sex therapy was originated and developed by Masters and Johnson. Dual-sex therapy does not accept the idea of a dysfunctional half of a patient couple. Both individuals are involved in a relationship in which there is sexual distress, and, thus, both should participate in the therapy program.

The sexual problem often reflects other areas of disharmony or misunderstanding in the marriage. The marital relationship as a whole is treated with emphasis on sexual functioning as a part of that relationship. Improved communication in sexual and nonsexual areas is a specific goal of treatment. Psychological and physiologic aspects of sexual functioning are discussed with an educational attitude. Suggestions are followed in the privacy of the couple's home.

Initial histories are taken to determine suitability for this type of treatment. Evidence of major underlying psychopathology suggests further psychiatric evaluation, and participation in the program may be deferred until the patient seems better able to benefit from it. Concurrent psychotherapy with a psychiatrist while participating in dual-sex therapy is sometimes recommended.

Each patient is interviewed individually early in the course of treatment. A complete sexual history is obtained, which is later reflected back to the couple to help them understand their present problem. For example, a history of culturally or parentally transmitted inhibition can help relieve the partner of an anorgasmic woman of the idea that he is a bad lover. Similarly, the partner of a man with erectile disorder may be relieved of the concern that his problem is a result of her being insufficiently attractive. The individual sessions also help the therapist understand the patients' lifestyle and allow for suggestions that fit into that lifestyle.

Behavioral Exercises. Treatment is short term and behaviorally oriented. Specific exercises are prescribed to help the couple with their particular problem. Sexual dysfunction often involves a fear of inadequate performance; thus, couples are specifically prohibited from any sexual play other than that prescribed by the therapist. Initially, intercourse is interdicted, and couples learn to give and receive bodily pleasure without the pressure of performance. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell.

During these exercises, called *sensate focus exercises,* the couple is given much reinforcement to lessen anxiety. They are urged to use fantasies to distract them from obsessive concerns about performance, which is termed *spectatoring.* The needs of both the dysfunctional partner and the nondysfunctional partner are considered. If either partner becomes sexually excited by the exercises, the other is encouraged to bring them to orgasm by manual or oral means. This procedure is important to keep the nondysfunctional partner from sabotaging the treatment. Open communication between the partners is urged, and the expression of mutual needs is encouraged. Resistances, such as claims of fatigue or not enough time to complete the exercises, are common and must be dealt with by the therapist. Genital stimulation is eventually added to general body stimulation. The couple is sequentially taught to try various positions for intercourse without necessarily completing the act and using varieties of stimulating techniques before they are permitted to proceed with intercourse.

The specific exercises vary with differing presenting complaints, and special techniques are used to treat the various dysfunctions. In cases of vaginismus, for instance, the woman is advised to dilate her vaginal opening with her fingers or with size-graduated vaginal dilators as part of the therapy. She may also be referred to a physiotherapist specializing in pelvic disorders. In cases of premature ejaculation, an exercise known as the *squeeze technique* is used to raise the threshold of penile excitability. In this exercise, the man or the woman stimulates the erect penis until the earliest sensations of impending orgasm and ejaculation are felt. Penile stimulation is then stopped abruptly, and the coronal ridge of the penis is forcibly squeezed for several seconds. The technique is repeated several times. A variation is the *stop–start technique,* in which stimulation is interrupted for several seconds, but no squeeze is applied. Masturbation to the point of imminent orgasm raises the threshold of excitability to a more tolerant stimulation level. The man is encouraged to focus on sensations of excitement rather than distract himself from them. This makes him more familiar with his excitement pattern and lets him feel in control rather than overwhelmed by sensations of arousal. Communication between the partners is improved because the man must let his partner know his level of sexual excitement so that she can squeeze the penis before the ejaculatory process has started. Sex therapy has been successful with some premature ejaculators; however, a subgroup of dysfunctional men may need pharmacotherapy as well.

A man with sexual desire disorder or erectile disorder is sometimes told to masturbate to demonstrate that full erection and ejaculation are possible. A woman with a lifelong female orgasmic disorder is directed to masturbate, sometimes using a vibrator. Kegel exercises may be introduced to strengthen the pubococcygeal muscles—that is, the woman is encouraged to contract her abdominal and perineal muscles during masturbation and coitus. When a man has an erectile disorder, the woman may be instructed to stimulate or tease his penis. The same technique is used with men who suffer from retarded ejaculation, with stimulation sometimes involving a vibrator. Delayed ejaculation is managed by extravaginal ejaculation initially and gradual vaginal entry after stimulation to the point of near ejaculation.

Treatment Goals. The overall goal of treatment is to initiate an educational process, to diminish the fears of performance felt by both sexes, and to facilitate communication in sexual and nonsexual areas. Therapy sessions follow each new exercise period, and problems and satisfactions (both sexual and nonsexual) are discussed. Specific instructions and new exercises geared to the individual couple's progress are reviewed in each session. Gradually, the couple gains confidence and learns (or relearns) to communicate verbally and sexually. Dual-sex therapy is most effective when the sexual dysfunction exists apart from other psychopathology.

Hypnotherapy

Hypnotherapists focus specifically on the anxiety-producing symptom—that is, the particular sexual dysfunction. Successful use of hypnosis helps the patient gain control over the symptom that has been lowering self-esteem and disrupting psychological homeostasis. Patient cooperation is first obtained and encouraged during a series of nonhypnotic sessions with the therapist, designed to develop a secure doctor–patient relationship and a sense of physical and psychological comfort on the part of the patient and to establish mutually desired treatment goals. During that time, the therapist assesses the patient's capacity for the trance experience. The nonhypnotic sessions also permit the clinician to take a careful psychiatric history and do a mental status examination before beginning hypnotherapy. Treatment focuses on symptom removal and attitude alteration. In a trance state, patients can entertain ideas incongruent with their usual (nonhypnotized) perceptions of reality. Patients are instructed in developing alternative means of dealing with the anxiety-provoking situation (i.e., the sexual encounter).

For example, a woman with vaginismus is given the posthypnotic suggestion that she will feel no pain during intercourse and will be able to relax the muscles surrounding her vagina. If compliance with the suggestion is successful, she can deal with the anxiety produced by the sex act. She is also taught new attitudes, such as being entitled to sexual pleasure. Under hypnosis, her fear or anger at sexual contact can be examined, and she learns how her emotions are expressed by involuntary vaginal spasms.

Some patients respond particularly well to the use of self-hypnosis and indirect suggestion. These techniques allow them to retain a greater sense of control over their situation. Typically, patients are instructed to conjure up images and develop ideas antithetical to their dysfunctional responses. For example, a woman with an arousal disorder may first agree to concentrate on imagery that causes her to salivate. She is then told that, just as she has made her mouth water by focusing on stimulating images, she can affect the lubricating response of her vagina by focusing on images she finds erotic or romantic. At the same time, the therapist helps her deal with her anxieties about a positive sexual response. Patients are also taught relaxing techniques to use before sexual relations. With these methods to alleviate anxiety, the physiologic responses to sexual stimulation can more readily result in pleasurable excitation and discharge. Hypnosis may be added to a basic individual psychotherapy program to accelerate the impact of psychotherapeutic intervention.

Behavior Therapy

Behavior therapists assume that sexual dysfunction is learned, maladaptive behavior. Behavioral approaches were initially designed to treat phobias. In cases of sexual dysfunction, the therapist sees the patient as phobic of sexual interaction. Using traditional techniques, the therapist sets up a hierarchy of anxiety-provoking situations for the patient, ranging from the least threatening to the most threatening. Mild anxiety may be experienced at the thought of kissing, and massive anxiety may be felt when imagining penile penetration. The behavior therapist helps the patient master the anxiety through a standard program of systematic desensitization. The program is designed to inhibit the learned anxious response by encouraging behaviors antithetical to anxiety. The patient first deals with the least anxiety-producing situation in fantasy and progresses by steps to the most anxiety-producing situation. Medication, hypnosis, or special training in deep muscle relaxation is sometimes used to help with the initial mastery of anxiety.

Assertiveness training helps teach patients to express their sexual needs openly and without fear. Exercises in assertiveness are given in conjunction with sex therapy, and patients are encouraged both to make sexual requests and to refuse to comply with requests perceived as unreasonable. Sexual exercises may be prescribed for patients to perform at home, and a hierarchy may be established, starting with activities that proved most pleasurable and successful in the past.

One treatment variation involves the participation of the patient's sexual partner in the desensitization program. The partner, rather than the therapist, presents the hierarchical items to the patient. In such situations, a cooperative partner is necessary to help the patient carry gains made during treatment sessions to sexual activity at home.

Behavior therapy techniques have been particularly effective in treating women with severe inhibition of excitement and orgasm when such feelings were accompanied by strong feelings of anxiety, anger, or disgust.

Group Therapy

Methods of group therapy have been used to examine both intrapsychic and interpersonal problems in patients with sexual disorders. The therapy group provides a strong support system for patients who feel ashamed, anxious, or guilty about a particular sexual problem. It is a useful forum in which to counteract sexual myths, correct misconceptions, and provide accurate information regarding sexual anatomy, physiology, and varieties of behavior.

Groups for the treatment of sexual disorders can be organized in several ways. Members may all share the same problem, such as premature ejaculation; members may all be of the same sex and have different sexual problems, or groups may be composed of both men and women who are experiencing different sexual problems. Group therapy may be an adjunct to other forms of therapy or the prime mode of treatment. Groups organized to cure a particular dysfunction usually have a behavioral approach. For example, patients with anorgasmia may participate with others who have the same problem in a short-term, intensive group experience. Sexual histories, feelings of inadequacy, and concerns about body image are shared. Specific physiologic information, sometimes with the aid of audiovisual materials, is presented to the group members. Members are given homework assignments (e.g., they may be instructed to masturbate). A combination of group support and group pressure helps the participants complete assignments some might otherwise avoid. As the short-term group process nears termination, members are encouraged to talk about their experiences with their partners.

Groups have also been effective when composed of sexually dysfunctional married couples. The group provides an opportunity to gather accurate information, provides consensual validation of individual preferences, and enhances self-esteem and self-acceptance. Such techniques as role-playing and psychodrama may be used in treatment. These groups are not indicated for couples in which one partner is uncooperative, has severe depression or psychosis, or has a strong repugnance for explicit sexual audiovisual materials or a strong fear of groups.

Integrated Sex Therapy

One of the most effective treatment modalities is the use of sex therapy integrated with supportive, psychodynamic, or insight-orientated psychotherapy. Adding psychodynamic conceptualizations to the behavioral techniques used to treat sexual dysfunctions allows treatment of patients with sex disorders associated with other psychopathology. Also, this type of therapy is appropriate for patients with hypoactive desire disorders or interest/arousal disorder. Insight-oriented therapy helps them deal with problems in their interpersonal relationships or intrapsychic conflicts that frequently are at the root of the problem. The themes and dynamics that emerge in patients in analytically oriented sex therapy are the same as those that emerge in psychoanalytic therapy—relevant dreams, fear of punishment, aggressive feelings, difficulty with trusting the partner, fear of intimacy, oedipal feelings, and fear of genital mutilation.

Mr. K, a 62-year-old divorced man, presented for therapy with a chief complaint of erectile dysfunction with his current partner, Miss B. They had been living together for 4 years. At the beginning of their relationship, they had had an active and nondysfunctional sex life. He was a successful businessman who met Miss B at a business convention where she was a hostess/welcomer at the convention center. Mr. K was very attracted to her. He also liked her poise and social ease and felt he could be proud of her.

Shortly after they began living together, he began seeing other women as well. Miss B eventually found out and insisted that he stop seeing other women. She also demanded that they get married. Mr. K agreed to stop his infidelities and agreed to become engaged. His erectile difficulties with Miss B, which had started somewhat before this confrontation, became persistent and pronounced. Even though he was able to achieve and maintain erections if he used sildenafil, he began avoiding sex with her altogether. He did not think of leaving the relationship (although he broke off the engagement) because he felt he was aging, feared loneliness, and lacked confidence that he could find another desirable woman. Also, he had experienced similar problems in his marriage and had enough insight to realize that his pattern of behavior was destructive. (Miss B had her own set of issues that kept her in the relationship.) She had become depressed but was more hopeful since Mr. K had agreed to start therapy.

Mr. K had a poised, secure façade, but he was hypersensitive to criticism, frequently felt like an outsider in social groups, relied on reassurance from women for his self-worth, and dealt with his anxieties with denial and sexual impulsiveness.

Mr. K’s issues reflected experiential and developmental problems. It had been hard for him to establish peer relationships growing up due to the family’s frequent travels and relocations. His father was a moderately successful, demanding man who was competitive with Mr. K and would send him into inappropriate situations. For example, he would send him on errands in a new location where, as a boy, Mr. K did not know his way around, and be critical of Mr. K if he failed in the errand; or he would tell him to “stand up for yourself” with boys who were substantially older and stronger than the patient. At the same time, Mr. K was his mother’s “darling, her everything.” Resulting unresolved oedipal issues made it difficult for him to direct both tender and passionate feelings toward the same woman. Unresolved dependency needs made it hard for him to discuss differences he had with Miss B in a constructive, assertive way, and he denied cumulative resentments (appropriate or inappropriate).

These issues were addressed in introspective psychotherapy. Miss B was also referred for individual therapy, and the couple was seen together for behaviorally oriented sex therapy.

The combined approach of individual and sex therapy is used by the general psychiatrist, who carefully judges the optimal timing of sex therapy and the ability of patients to tolerate the directive approach that focuses on their sexual difficulties.

Biologic Treatment Methods

Biologic treatments, including pharmacotherapy and surgery, have applications in specific cases of sexual disorder. Advances in biologic treatment methods, particularly pharmacologic methods of treating sexual dysfunction, have significantly augmented the therapist's catalog of therapeutic approaches. Most of the recent advances involve male sexual dysfunctions. Current studies are under way to test pharmacologic treatment of sexual dysfunctions in women. Flibanserin is a drug approved by the U.S. Food and Drug Administration (FDA) to treat low sexual interest in women. Questions about the drug included a report of a minimal increase in desire during trials and concerns about side effects, particularly hypotension and syncope. Physicians must undergo a certification process to prescribe flibanserin.

Pharmacotherapy. A variety of drugs have been explored in the treatment of male sexual dysfunction. The major medications used are nitric oxide enhancers such as sildenafil (Viagra); oral prostaglandin (Vasomax); alprostadil (Idex), injectable phentolamine; and transurethral alprostadil (MUSE), all used in the treatment of erectile disorder.

NITRIC OXIDE ENHANCERS. Nitric oxide enhancers facilitate the inflow of blood to the penis necessary for an erection. The physiologic mechanism of penile erection involves the release of nitric oxide in the corpus cavernosum during sexual stimulation. Nitric oxide activates the enzyme guanylate cyclase, which increases cyclic guanosine monophosphate concentration and produces smooth muscle relaxation in the corpus cavernosum that allows the penile vessels to dilate and admit blood. The first drug developed, sildenafil enhances the effect of nitric oxide by inhibiting the enzyme that degrades cyclic guanosine monophosphate. Thus, sildenafil augments the natural process involved in gaining and maintaining an erection during sexual stimulation. The drug takes effect approximately 1 hour after ingestion, and its effect can last up to 4 hours. Sildenafil has no effect in the absence of sexual stimulation.

The most common adverse events associated with sildenafil are headaches, flushing, and dyspepsia. Some sildenafil users see things in a blue tint for several hours after taking the medication; because of this, airline pilots have been prohibited from taking the drug so that this visual artifact does not interfere with safe landings. A more serious visual side effect is the loss of visual acuity and nonarteritic anterior ischemic optic neuropathy resulting in blindness. Although the occurrence is extremely rare, phosphodiesterase type 5 inhibitors should not be used with men with serious optic pathology. The use is also contraindicated for people taking organic nitrates. The concomitant action of the two drugs can result in large, sudden, and sometimes fatal drops in systemic blood pressure. The U.S. FDA has posted 522 deaths as of 2014, in which sildenafil was listed as an associated medication and advises caution in prescribing sildenafil to men with a recent (6-month) history of myocardial infarction, stroke, life-threatening arrhythmia, significant hypotension or hypertension, cardiac failure, angina, or retinitis pigmentosa. Sildenafil has also been implicated in cases of deafness. One study of Swedish men using phosphodiesterase 5 inhibitors found a modestly significant correlation between use and the presence of malignant melanoma. The researchers stated that this association was not proved to be causal. In association with side-effect alerts, the FDA has reiterated that it is a safe drug. Sildenafil is not effective in all cases of erectile dysfunction. It fails to produce an erection rigid enough for penetration in approximately 50% of men who have had radical prostate surgery or in those with long-standing, insulin-dependent diabetes. It is also ineffective in certain cases of nerve damage.

Two other nitric oxide enhancers similar to sildenafil—vardenafil (Levitra) and tadalafil (Cialis)—have been developed. Tadalafil has an effective therapeutic window of 36 hours compared to sildenafil and vardenafil, which are effective for approximately 4 hours.

Oral phentolamine has proved effective as a potency enhancer in men with minimal erectile dysfunction. It may prove useful for men with cardiac problems, as sildenafil is contraindicated for men using organic nitrates, but it is not currently approved by the FDA. Apomorphine is also being tested as an oral remedy for erectile dysfunction.

ALPROSTADIL. In contrast to the oral medications, injectable and transurethral alprostadil act locally on the penis and can produce erections in the absence of sexual stimulation. Alprostadil contains a naturally occurring form of prostaglandin E. Prostaglandins are composed of complex hydroxy fatty acids, and they have wide biologic influences. Although some prostaglandins are vasoconstrictive, prostaglandin E_1, found in alprostadil, is a powerful vasodilating agent, especially in local vascular areas, such as the corpus cavernosum of the penis. The drug causes direct smooth muscle relaxation of penile vessels and erectile tissue; this reaction lowers the vascular resistance of the corpus and significantly increases blood flow to the penis. The firm erection produced within 2 to 3 minutes by increased blood flow may last as long as 1 hour. Treatment consists of the patient’s self-injection of alprostadil into the corpus before coitus. This technique is easily taught and relatively painless. Infrequent adverse effects include penile bruising and changes in liver function test results, which are readily reversible when a man stops the injections. However, possible hazardous sequelae exist, including priapism and sclerosis of the small veins of the penis. In some men for whom alprostadil was not effective, an injection of Trimix, a combination of prostaglandin E, phentolamine (an αl-adrenergic antagonist), and papaverine (a nonspecific phosphodiesterase inhibitor) produced an erection. Another substance being tried is a vasoactive intestinal polypeptide (VIP). Intracavernous injection of VIP causes erection and has a parasympathomimetic effect. Some researchers speculate that this substance, which has been found in the hypothalamus and the female genital organs, is the essential factor in male and female arousal. In Europe, phenoxybenzamine (Dibenzyline) is used to produce erections by injection into the penis. Serious adverse effects include priapism and pain accompanying the injection, and the drug is not allowed as a therapy in the United States.

Alprostadil can also be delivered via the urethra, eliminating the need for self-injection. Some men prefer the local, nonsystemic effects of alprostadil to oral sildenafil; others prefer sildenafil because it seems more like a nonpharmacologically aided response to them and their partners. A small trial found a topical cream effective in alleviating erectile dysfunction. The cream consists of three vasoactive substances that are a mixture of ergot alkaloids. Alprostadil is a useful treatment for patients in whom nitric oxide enhancers are contraindicated (e.g., patients who are taking nitrate-containing medication). It is also of use in patients who do not tolerate the side effects of other drugs and may work for some patients who have found sildenafil ineffective, for example, in some postprostatectomy patients.

The pharmacologic treatments described above are useful in the treatment of erectile dysfunction of various causes: psychogenic, neurogenic, arterial insufficiency, venous leakage, and mixed.

Mr. J presented for therapy with a chief complaint of erectile disorder. He was a 49-year-old man who had been divorced for 6 years after a marriage of 12 years duration. Although he suffered no erectile dysfunction in his marriage, and in fact, experienced strong desire, his wife refused to have sex with him in the last 2 years of their marriage. By that time, their relationship had seriously deteriorated. Although it was Mr. J's decision to end the marriage, he felt hurt and humiliated by his ex-wife's sexual rejection and was wary of ever committing to someone else. His sense of rejection evoked memories of a painful adolescence when he had felt very inadequate with girls and was fearful of being mocked by male peers. After his divorce, he had a series of dating relationships with women but suffered from recurrent erectile disorder with all of them.

When he came for therapy, he was in the midst of a new relationship. The patient was prescribed sildenafil, 50 mg, but he was reluctant to tell his girlfriend that he was taking a medication to help him function sexually. Instead, he avoided sex with her. Several therapy sessions were devoted to encouraging him to share his sexual problem with her. He finally did so, and his girlfriend, a woman with confidence in her sexuality, was accepting of his problem. In fact, she encouraged him to take the sildenafil. After 3 months of an active sex life without erectile problems, Mr. J was told to try intercourse without sildenafil. With the emotional support of his girlfriend, he made a successful attempt at coitus. The patient continues to use sildenafil occasionally. The knowledge that he has a "backup" to help him with his erection if he is feeling very anxious or stressed enables him to maintain a normal active sex life.

Erectile dysfunction of psychological or mixed origin should not be treated by medication alone, even though the dysfunction can be corrected pharmacologically. The drugs should be used in conjunction with, not as a replacement for, sex therapy. In some cases, erectile dysfunction serves as a defense against unconscious conflicts that must be faced when the sexual symptom is removed as a result of medication. In some cases, the patient deals with his conflicts by simply not using the medications prescribed for his erectile problem. Also, patients in long-standing or marital relationships require the cooperation of their partners for this treatment to be effective. Although most women are very accommodating to their partner's desire for treatment, several concerns occur with some frequency: the element of romance is an important part of sexual interaction for many women, and pharmacologic assistance of erections may eliminate that sense of romance; the woman, or the couple, may bemoan the lack of spontaneity when pharmacotherapy is part of the sex act; and some women feel deprived of feedback about their desirability. Joint sessions help the couple cope with these issues.

SILDENAFIL USE IN WOMEN. The physical sign of sexual excitement in women is vaginal lubrication. That lubrication is a transudate believed to result from increased vasocongestion of the extensive capillary net surrounding the vaginal walls. The same physiologic mechanism—vasocongestion—results in erection in the man. Researchers believe that sildenafil may facilitate blood flow in women just as it does in men and, thus, give women with inhibited excitement of psychological or physiologic origin a pharmacologic remedy for their dysfunction. Some reports suggest that women find it preferable to apply sildenafil in a cream base to the clitoris, labia, and vagina. However, as in men, pharmacologic treatment may need to be combined with psychological modalities to be effective.

Recognition of sexual excitement may be more complex for women than it is for men. For example, in studies of response to pornography, men and women underwent physiologic measurements of excitement after visual stimuli. In these studies, men were more accurate in correlating their subjective sense of arousal with physiologic arousal (i.e., erection) than were women (i.e., lubrication).

Other Pharmacologic Agents

ANTIDEPRESSANTS. The side effects of antidepressants, particularly the SSRIs, which include delayed orgasm, have been used to prolong the sexual response in patients with premature ejaculation. This approach is particularly useful in patients refractory to behavioral techniques or who may have physiologically determined premature ejaculation. Daily treatment is recommended. The SSRIs vary in their ability to delay ejaculation, with paroxetine (20 to 40 mg) being the most effective, followed by clomipramine (10 to 50 mg), sertraline (50 to 100 mg), fluoxetine (20 to 40 mg), citalopram (20 to 40 mg), and escitalopram (10 to 20 mg). On-demand use of SSRIs can be tried but is less effective. However, on-demand use of clomipramine (20 to 40 mg) may delay ejaculation after 4 to 6 hours, although it may lead to nausea on the same day or the next day. Long-term adverse effects of daily SSRI use include weight gain with its associated risk for type 2 diabetes mellitus. Also, depressed patients must be monitored for suicidal thoughts, and bipolar patients monitored for mania. Other on-demand treatments for premature ejaculation include topical anesthetics such as lidocaine or prilocaine cream or spray, which is applied to the glans of the penis. Use must be titrated to prevent sufficiently strong anesthesia that interferes with erection. Sometimes condom use is necessary to prevent vaginal numbness.

Other Pharmacologic Agents. Numerous other pharmacologic agents have been used to cure various sexual disorders. Intravenous methohexital sodium (Brevital) has been used in desensitization therapy. Antianxiety agents may have some application in tense patients, although these drugs can also interfere with the sexual response. The use of antidepressants has been advocated in the treatment of patients who are phobic of sex and in those with a post-traumatic stress disorder (PTSD) after rape. Bromocriptine (Parlodel) is used in the treatment of hyperprolactinemia, which is frequently associated with hypogonadism. Such cases are first worked up to rule out pituitary tumors. Bromocriptine, a dopamine agonist, may improve sexual function impaired by hyperprolactinemia.

Yohimbine is an α-adrenergic receptor antagonist that may cause dilation of the penile artery and improve erections. Recreational drugs, including cocaine, amphetamines, alcohol, and cannabis, are considered enhancers of sexual performance. Although they may provide the user with an initial benefit because of their tranquilizing, disinhibiting, or mood-elevating effects, consistent or prolonged use of any of these substances impairs sexual functioning.

Ginseng has been reported to have androgenic effects. One report described the case of a mother who ingested large amounts of ginseng during her pregnancy, resulting in androgenization of the neonate, who was born with pubic hair and enlarged testes.

Other drugs that have been used by women to alleviate arousal dysfunction include oral phentolamine, topical prostaglandin E, oral oxytocin, ginkgo biloba, and various psychostimulants, including caffeine. Many of these drugs have not been approved for the treatment of female sexual dysfunction and must be prescribed with caution.

Dopaminergic agents have been reported to increase libido and improve sex function. Those drugs include L-dopa, a dopamine precursor, and bromocriptine, a dopamine agonist. The antidepressant bupropion has dopaminergic effects and has increased sex drive in some patients. Selegiline, an MAOI, is selective for MAO_B and is dopaminergic. It improves sexual functioning in older persons.

HORMONE THERAPY. Androgens increase the sex drive in women and in men with low testosterone concentrations. Women may experience virilizing effects, some of which are irreversible (e.g., deepening of the voice). This problem is avoided if the woman applies a mild (compounded) testosterone ointment to her labia, inner thighs, or abdomen. Ongoing care by an endocrinologist is necessary for women who require more intensive testosterone treatment. Testosterone can be administered to men through injections, transdermal patches, or as gels, creams, or pellets. Oral preparations are associated with an increased risk of hepatotoxicity. Side effects may include hypertension and prostate enlargement, among other side effects. However, recent studies question effects on the prostate.

Clomiphene, usually used as a fertility drug for women, also stimulates testosterone production in men by action on the pituitary–gonad feedback cycle.

Gonadotrophin-releasing hormone (GnRH), also known as *luteinizing hormone–releasing hormone* (LHRH), stimulates the release of luteinizing hormone, which increases testosterone secretion in both sexes. GnRH is used as an inhalant in Europe. It stimulates desire and increases potency. Because GnRH is released normally in a pulsatile fashion, portable infusion pumps have been developed that simulate pulsatile delivery. An excess of GnRH suppresses estrogen and testosterone; thus, the therapeutic use of GnRH is limited by a narrow therapeutic window.

Women who use estrogens for HRT or for contraception may report decreased libido; in such cases, a combined preparation of estrogen and testosterone has been used effectively. Estrogen itself prevents thinning of the vaginal mucous membrane and facilitates lubrication. It may also increase tactile sensitivity. Vaginal estrogen creams have been helpful to postmenopausal women who cannot take HRT due to their medical or family history.

Testosterone is given to women around the world in the form of tablets, implants, patches, and creams. In the United States, methyltestosterone pills and compounded creams are the primary methods of administration. Testosterone is primarily administered to postmenopausal (occurring surgically or naturally) women, but testosterone deficiency also exists in premenopausal women.

Mrs. M presented for therapy alone with a chief complaint of pain on intercourse dating from the onset of menopause 14 months before coming for treatment. Her husband knew of her visit but did not accompany her, as he was away on one of many routine and frequent business trips.

Sexual intercourse was infrequent because of his heavy travel schedule, but their sex play was varied, and, before menopause, Mrs. M had enjoyed sex. Mrs. M found her sexual interactions with her husband gratifying. She had a strong libido and would masturbate when Mr. M was away.

Mrs. M was on oral HRT, which had helped but had not eliminated the pain she had with intercourse. In consultation with her gynecologist, the occasional use of hormone cream was added to her treatment regimen. In addition, she was instructed to use vaginal dilators routinely when Mr. M was away. This was not for purposes of masturbation, which for her involved clitoral stimulation, but for routine stretching of the vagina. Nonhormonal vaginal cream was prescribed for the couple to use with intercourse. The combination of oral HRT, vaginal creams, and the routine use of vaginal dilators served to eliminate Mrs. M’s pain. She was diagnosed with sexual dysfunction due to a general medical condition.

Pheromones are sexual scents that are found in animals and may be present in humans. They produce dramatic sex-seeking behavioral patterns in animals (e.g., male deer following female deer in estrus, mounting behavior in primates). Human pheromones are believed to be short-acting fatty acids present in vaginal secretions and male sweat. In one study, women were consistently more attracted to items impregnated with a chemical derived from male sweat (α-androstenol) than to control items. In another study, the sweat of women was preserved in underarm pads they changed daily, and the date each pad was worn was correlated with the women's menstrual cycle. A second group of women was asked to smell these pads as they were rubbed above their upper lips, without knowing what they were and recognizing no scent but the alcohol preservative used on the pads. Depending on whether they were exposed to pads from the early or late part of the first group's (the wearers) menstrual cycle, the second group (the sniffers) saw their own menstrual cycles shortened or lengthened. This area is still being researched.

ANTIANDROGENS AND ANTIESTROGENS. Estrogen and progesterone are antiandrogens that have been used to treat compulsive sexual behavior in men, usually in sex offenders.

Medroxyprogesterone acetate (Depo-Provera), used primarily as a contraceptive in women, inhibits the secretion of gonadotropins. It is used in men with compulsive sexual behavior to reduce libido by lowering testosterone levels. Cyproterone acetate is a strong antiandrogen used in Europe to treat sex offenders. At dosages of 100 to 200 mg a day, the sex drive disappears within 2 weeks.

Tamoxifen (Nolvadex) is used to treat breast cancer and has antiestrogenic properties. In some women, increased libido may result from unopposed testosterone levels. Clomiphene (Clomid) is an ovulatory stimulant used in women with anovulatory menstrual cycles desiring pregnancy. Clomiphene increases the release of pituitary gonadotropins, and some women may report increased libido. Neither of these drugs, however, is used as a treatment for decreased sexual interest in women.

Mechanical Treatment Approaches

STEAL SYNDROME. In male patients with arteriosclerosis (especially of the distal aorta, known as *Leriche syndrome*), the erection may be lost during active pelvic thrusting. The need for increased blood in the gluteal muscles and others served by the ilial or hypogastric arteries takes blood away (steals) from the pudendal artery and, thus, interferes with penile blood flow. Relief may be obtained by decreasing pelvic thrusting, which is also aided by the woman-superior coital position.

VACUUM PUMP. Vacuum pumps are mechanical devices that patients without vascular disease can use to obtain erections. The blood drawn into the penis after the creation of the vacuum is kept there by a ring placed around the base of the penis. This device has no adverse effects, but it is cumbersome, and partners must be willing to accept its use. Some women complain that the penis is redder and cooler than when erection is produced by natural circumstances, and they find the process and the result objectionable.

A vacuum pump with the marketing name *Eros* was devised for women to precipitate a clitoral erection. It works similarly to the vacuum pump used to create penile erections in men, although no band is placed around the clitoris once erection is obtained. The pump is not necessary for intercourse to occur; it was devised to enhance female excitement, but its effectiveness has not been studied rigorously.

Surgical Treatment

MALE PROSTHESES. Surgical treatment is infrequently advocated, but improved penile prosthetic devices are available for men with inadequate erectile response who are resistant to other treatment methods or who have medically caused deficiencies. For instance, it is used in some cases of Peyronie disease when more conservative treatments have been unsuccessful. There are two main types of prosthesis: a semirigid rod prosthesis that produces a permanent erection that can be positioned close to the body for concealment and an inflatable type that is implanted with its own reservoir and pump for inflation and deflation. The latter type is designed to mimic normal physiologic functioning. Placing a penile prosthesis in a man who has lost the ability to ejaculate or to have an orgasm as a result of medical causes will not restore those functions. Men with prosthetic devices have generally reported satisfaction with their subsequent sexual functioning, but their wives report much less satisfaction. Presurgical counseling is strongly recommended so that the couple has a realistic expectation of what the prosthesis can do for their sex lives. Postsurgical counseling may also be necessary to help the couple adapt to their rediscovered ability to have intercourse. They might experience a high level of anxiety if their sex life was inactive for a prolonged period before surgery. Prosthetic devices have been associated with severe adverse effects, including perforation, infection, urinary retention, and persistent pain.

Some surgeons are attempting revascularization of the penis as a direct approach to treating erectile dysfunction resulting from vascular disorders. Such surgical procedures are indicated in patients with corporal shunts that allow normally entrapped blood to leak from the corporal spaces, leading to inadequate erections (steal syndrome). Limited reports exist of prolonged success with the technique. Endarterectomy can be of benefit if aortoiliac occlusive disease is responsible for erectile dysfunction.

Another medical treatment being studied for erectile disorders is electrostimulation at the base of the penis. Initial reports indicate minimal physical discomfort in patients receiving this therapy. However, the response to treatment is inconsistent, and a problem exists in terms of maintaining erections. At the present time, the treatment seems to have no benefits.

FEMALE PROCEDURES. Surgical approaches to female dysfunctions include hymenectomy in the case of dyspareunia in an unconsummated marriage, vaginoplasty in multiparous women complaining of lessened vaginal sensations, or freeing clitoral adhesions in women with inhibited excitement. Such surgical treatments have not been carefully studied and should be considered cautiously.

Outcome. Demonstrating the effectiveness of the varieties of sex therapy is just as difficult as assessing the effectiveness of outpatient psychotherapy in treating other psychological problems. As with other disorders, the more severe the psychopathology associated with a problem of long duration, the more adverse the outcome is likely to be.

The most difficult treatment cases involve couples with severe marital discord. Cases involving problems of fear of intimacy, excessive dependency, or excessive hostility are also complex. Other challenges are posed by patients with impulse disorders, unresolved conflicts about sexual orientation, or fetishistic defenses. Patients with acquired dysfunctions have a better prognosis than do patients with lifelong dysfunctions. Disorders of desire or interest require longer, more intensive therapy than some other disorders, and their outcomes are very variable.

When behavioral approaches are used, empirical criteria that are supposed to predict outcomes are more easily isolated. Using these criteria, for instance, couples who regularly practice assigned exercises appear to have a much greater likelihood of successful outcome than do more resistant couples or those whose interaction involves sadomasochistic or depressive features or mechanisms of blame and projection. Flexibility of attitude is also a positive prognostic factor. Overall, younger couples tend to complete sex therapy more often than older couples. Couples whose interactional difficulties center on their sex problems, such as inhibition, frustration, or fear of performance failure, are also likely to respond well to therapy.

Methods that have proved effective singly or in combination include training in behavioral sexual skills, systematic desensitization, directive marital counseling, traditional psychodynamic approaches, group therapy, and pharmacotherapy. Although most clinicians prefer to treat a couple for sexual dysfunctions, treatment of individual persons has also been successful. The frequency of sessions is not a significant factor in treatment success. Thus, whether patients have intensive daily therapy over a period of 2 weeks, weekly therapy, or biweekly therapy appears to have little effect on the outcome of treatment. Also, the use of one therapist to treat a couple instead of a dual-sex cotherapy team is nearly as effective and certainly more practical. A multimodal regimen and an eclectic approach are frequently necessary to treat sexual disorders. Many couples who do not reach their ideal goal of sexual interaction, nonetheless, report considerable improvement and satisfaction in their sex lives and their general sense of well-being.

CULTURAL MORES AND SEXUALITY

Cultural mores affect the societal acceptance, legality, and self-perception of normal sexual behavior. An overview of the mores of Western civilization reveals a pendulum that oscillates between the liberal and the puritanical, between tolerance and restriction of behaviors, and between acceptance or repression of human sexuality. Mores are affected by knowledge, superstition, scientific advances, and religion, in addition to the outbreak of sexually transmitted infections and types of government. Proscription of sexual behavior goes back to the beginning of recorded time. The Book of the Dead in Egypt, 6,000 years ago, the Code of Hammurabi, and the Hittite Code, all had prohibitions against adultery.

Other sexual behaviors such as rape and sexual abuse of children have been condemned by law and public opinion across time.

In different eras, there are many examples of cultural swings in sexual attitudes. In the classical era, sensuality was characteristic of Greek life. There was a double standard, however. Women were not allowed the same sexual freedom permitted to men. Homosexuality was acceptable among men. By contrast, the Middle Ages was a time of sexual repression. Sexual behavior was restricted to marriage; contraception and abortion were condemned, and homosexuality was punishable by death. The Victorian era was a study in hypocrisy. Women and children were believed to have no sexual feelings, and the Victorians displayed a near obsession with masturbation inventing numerous outcomes such as blindness and insanity. At the same time, a sexual subculture existed, with prostitution and pornography prevalent. In the current era, sexual liberality has emerged. There are many contributing factors: the invention of the automobile, which allowed young adults to court without chaperones; the research of men like Kinsey bringing the discussion of sexual behavior into the public arena; the development of the birth control pill; the adjudication of Roe v. Wade, and societal movements including feminism and the civil rights movement that changed former societal attitudes.

Finally, it is apparent that a segment of society always challenges the prevalent cultural mores. If the attitudes are liberal, there are countervailing forces pushing for restrictive mores; if the prevailing attitudes are repressive, a segment in society will push for more sexual freedom. Above, I mentioned that changes regarding sexuality involved greater legal and societal acceptance of behaviors formerly considered abnormal. Currently, however, there are opponents of birth control, abortion, sex education in schools, sex outside of marriage, and the acceptance of transgendered persons. Support for those ideas is increased by the fear of sexually transmitted diseases, by cries that the family and society are disintegrating because of immoral sexual behavior, and when sexual freedom is used as a substitute for intimate relationships. Whatever the predominant values, different views challenge the status quo, exerting pressure on the pendulum of sexual mores to swing again in the opposite direction.

21.2 Homosexuality, Gay and Lesbian Identities, and Homosexual Behavior

JACK DRESCHER, M.D., AND WILLIAM M. BYNE, M.D., PH.D.

Historically, homosexuality was considered to be a social problem whose origins were attributed to any number of problematic causes, including sin, degeneracy, poor parenting, social delinquency, and mental illness. Today, psychiatry and other mental health professions have adopted a model of sexual orientation that regards same-sex attractions, behaviors, and relationships as normal variations of human sexuality. This normal variation model informs positions taken by the American Psychiatric Association (APA), the American Psychological Association, and the American Psychoanalytic Association (APsaA) in support of equal rights for people who experience same-sex attractions, including marriage equality (same-sex marriage). In retrospect, these current positions were the inevitable outgrowth of the APA's 1973 conclusion that homosexuality is not a mental disorder and its decision to remove homosexuality per se from its *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Not only did this action play a major role in the cultural normalization of same-sex relationships in the United States, but APA's diagnostic reclassification had an international impact as well. In 1990, the World Health Organization (WHO) removed the diagnosis of "homosexuality" *per se* from the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Although "homosexuality" was replaced by F66 codes (other sexual disorders, including ego-dystonic sexual orientation), in 2019, WHO deleted these codes and any remaining diagnoses that pathologize homosexuality from ICD-11. ICD-11 officially comes into effect in January of 2022, at which time member nations may begin reporting morbidity and mortality statistics using the updated nosology.

In light of these changes in diagnostic systems, the focus of mental health interventions has shifted dramatically. Where psychiatry and medicine once focused on questions like “What causes homosexuality?” or “Can homosexuals be converted to heterosexuals?,” today’s mental health policy foci with respect to sexual orientation increasingly concern the mental health needs of sexual minority people, including those who identify as lesbian, gay, or bisexual (LGB). This shift from historical pathologic models of same-sex attractions and behavior to a normal variant model has been accompanied by dramatically increased social acceptance of openly LGB individuals in many, although not all, cultures. Acceptance has evolved rapidly in the West. For example, the 8th edition of this chapter published in 2004 noted that same-sex marriage was then only legal in Belgium and the Netherlands. At the time of this writing, in 2021, same-sex marriage is available in 29 countries: Argentina, Australia, Austria, Belgium, Brazil, Canada, Colombia, Costa Rica, Denmark, Ecuador, Finland, France, Germany, Iceland, Ireland, Luxembourg, Malta, Mexico, the Netherlands, New Zealand, Norway, Portugal, South Africa, Spain, Sweden, Taiwan, the United Kingdom, the United States, and Uruguay. In 2013, in *United States v. Windsor*, the U.S. Supreme Court overturned Section 3 of the discriminatory Defense of Marriage Act (DOMA) that prevented the federal government from recognizing same-sex marriages in states where such marriages were legal. The Court went a step further in 2015 in *Obergefell v. Hodges,* a ruling that overturned 13 remaining state constitutional bans and made same-sex marriage legal in all 50 states. Civil unions, although providing fewer legal protections than marriage, at the time of this writing, are available in Chile, Croatia, Cyprus, Czech Republic, Estonia, Greece, Hungary, Italy, Lichtenstein, Northern Ireland, Slovenia, and Switzerland.

Another indicator of increased acceptance of LGB people is decreased prohibitions against them serving openly in the militaries around the world. In 2011, the U.S. Congress repealed “Don’t Ask, Don’t Tell,” a policy that prevented LGB gay people from serving openly in the United States armed forces. Currently, LGB people can serve openly in the militaries of over 50 countries.

On the other hand, while there has been increased acceptance of same-sex attraction and behavior in an increasing number of countries, this is not the case throughout the world. In 2013, Russia passed a law criminalizing the distribution of “propaganda” to minors that support “nontraditional sexual relationships,” generally taken as meaning same-sex relationships and behavior. Other former Soviet states and countries in

Eastern Europe, Hungary, and Poland, for example, have passed similar laws. Engaging in homosexual behavior is still considered a crime in almost 70 countries, many of which are in Africa, and in some countries, homosexuality is punishable by imprisonment (i.e., Algeria, Bangladesh, Egypt, Malaysia) or death (i.e., Afghanistan, Iran, Iraq, Nigeria). Despite efforts by the United Nations and other international human rights groups to have such legislation repealed, some African countries such as Gambia, Nigeria, and Uganda recently passed laws increasing criminal penalties for expressions of or even support for homosexuality.

Despite the social gains noted above, relative to their heterosexual counterparts, LGB men and women may exhibit multiple mental health problems, including higher frequencies of psychiatric problems such as anxiety disorders, depression, suicidality, and alcohol and substance abuse. A preponderance of evidence suggests that the excess mental health burden is not due to homosexuality, per se, but instead derives from the chronic stresses that accompany sexual minorities' stigmatized social status and living in a society with deeply embedded heterosexist attitudes. Recent efforts have focused on informing mental health practice with LGB individuals based on empirical research. Based on a review of this evidence, psychologist John Panchankis identified the following as candidates to adapt for evidence-based practice with sexual minorities: identity concealment, rejection hypervigilance, and internalized stigma. Practices based on high-quality empirical research hold promise for optimizing the mental health care of LGB patients.

DEFINITIONS

Common terms used to describe human sexuality have a range of meanings, not only in common parlance but among medical professionals and authoritative texts as well. The definitions of these terms as they are used in this chapter are presented here. *Sexual orientation* refers to a person's erotic response tendencies or sexual attractions, be they directed toward individuals of the same-sex (*homosexual*), the other sex (*heterosexual*), both sexes (*bisexual*), or neither (asexual). The terms homosexual and heterosexual can lead to confusion when used to describe the sexual orientation of people whose gender identity differs from the sex they were assigned at birth (i.e., people often collectively subsumed under the umbrella term *transgender;* see chapter 21.4 on gender identity). Increasingly in the United States, sexual orientation is described relative to one's gender identity rather than the sex to which one was assigned at birth. For example, the sexual orientation of a transgender man (someone assigned female at birth who now identifies as a man) who is sexually attracted to women could be described as heterosexual or *straight.* Sexual orientation may be described unambiguously independent of one's gender identity as *androphilic* (attracted to men), *gynephilic* (attracted to women), bisexual (attracted to both men and women), or *analophilic* (attracted to neither). Importantly, in conversations with patients, clinicians should use the sexual orientation labels that the patient uses. However, it is helpful to clarify how the patient defines their self-label.

Sexual orientation and *sexual preference* are sometimes used interchangeably, but the former term has a wider currency in contemporary professional and popular usage. Sexual orientation is the term most experts use, while "sexual preference" is a less precise term as it implies a volitional or voluntary component. While the decision to engage in sexual behavior is volitional, the preponderance of evidence suggests that the direction(s) of one's erotic responsiveness is not. Collectively, individuals whose sexual orientation is other than heterosexual are increasingly referred to as *sexual minorities.* Opponents of LGB rights (historically referred to *as gay or gay and lesbian rights, etc.*) have claimed paraphilic desires and disorders (see Paraphilias section) are also "sexual orientations." However, this is neither a widely held view nor how the term, paraphilia, is usually interpreted in either science or in antidiscrimination legislation. Sexual orientation is often described as having three components—desire, behavior, and identity—which may or may not be congruent in an individual; however, while all three are related to sexual orientation, the object(s) of one's sexual desire (i.e., men, women, both, neither) correspond(s) most closely to the definition of sexual orientation above.

The Heterosexual-Homosexual Rating Scale, better known as the Kinsey Scale, is a 7-point continuous scale, with 0 representing exclusive heterosexuality, 6 representing exclusive homosexuality, and 3 representing equal amounts of both—has been widely used in the study of sexual orientation. The Kinsey scale has been criticized for its unidimensional conceptualization of sexual orientation, suggesting a diminished attraction toward one sex may be proportional to an increased attraction to the other sex. Because fantasies/desires are not always congruent with an individual’s behaviors, each can be assessed separately using the Kinsey scale. While sexual desire and sexual behavior can be described quantitatively (e.g., the proportion of times that sexual activities are with men vs. women, the relative strength of attraction to men vs. women, etc.), sexual identity tends to be described categorically (e.g., heterosexual, homosexual, bisexual, asexual, unsure) and does not lend itself to quantification with the Kinsey scale (see “Homosexuality and Nongay Identities,” below). Further, the Kinsey scale is a research instrument and has no clinical utility beyond illustrating the point that individuals’ sexual desires and behaviors are not necessarily exclusively either homo- or heterosexual. Finally, scores on the Kinsey scale are based on reported self-appraisals rather than objective measures.

Sexual identities sometimes referred to as *sexual orientation identities,* refer to how individuals view and label themselves based on their subjective experience of their sexuality and the meanings they attribute to their sexual desires and behaviors. In the case of *homosexual, lesbian, gay,* or *bisexual* identities, these usually involve some measure of self-acceptance of one’s homosexual desires and perhaps identification with a community of similar others by virtue of having the same pattern of sexual attractions. This community is often referred to as the LGB community. The LGB acronym is often extended to LGBT in recognition of the fact that sexual minorities and gender minorities (e.g., transgender/transsexual individuals) are subject to similar stigma. More recently, the acronym has been extended by adding “Q” to represent people who are questioning their sexual or gender identity or who identify as queer, and by adding “+” to acknowledge additional sexual or gender minority groups, including those who identify as asexual or intersex. The acquisition of an identity as a sexual minority person is often conceptualized as a developmental process that occurs over time. Models of the development of LGB identities usually portray a series of progressive stages involving tasks such as *coming out* (the process of recognizing that one experiences same-sex attractions and acknowledging that fact to oneself and others), involvement in LGB communities, perhaps establishing same-sex romantic relationships, and integrating one’s sexual minority identity into other aspects of the self.

Importantly, not all persons who experience homoerotic desire or participate in homosexual behavior follow such a linear path or develop an enduring LGB identity. In addition to sexual orientation, the terms *gay,* *lesbian, bisexual, etc.,* may be used to signify identities based on one's recognition of and identification with similar others on the basis of sexual orientation. Thus, some individuals may acknowledge their homosexual orientation without identifying as gay, lesbian, or bisexual. For example, some identify as nongay homosexuals. In other words, a *sexual orientation identity* (aka *sexual identity*) is not synonymous with *sexual orientation.* Years may elapse between one's first awareness of same-sex attractions and integration of that awareness into one's sexual orientation identity, that is, identifying as an LGB or other sexual minority person. Sometimes such integration does not occur.

For example, a woman or man with a homosexual or bisexual orientation may not accept having same-sex attractions or may believe that such feelings are transitory. Such an individual might marry a member of the other sex and maintain an ostensibly heterosexual lifestyle. Such persons may never lose their same-sex desires and, even if consciously aware of them, still may not identify as gay, lesbian, or bisexual. Such a person may have a history of same-sex sexual behaviors and may even form homosexual relationships while at the same time expressing disdain for the gay or lesbian "lifestyle" and the LGB community. Such an individual, if bothered by their same-sex attractions, may seek religious or professional help to rid themselves of them. Some such individuals refer to themselves as "ex-gays." Research on whether people can actually change their sexual orientation through willful effort (see "Sexual Orientation Conversion Efforts," below) is not persuasive, although the issue recurrently generates cultural controversy in some quarters. It is clear that individuals can project a public image as heterosexual individuals but not clear at all that one can change their sexual orientation by volition. Other individuals, some of whom refer to themselves as "nongay homosexuals," may acknowledge their homosexual orientation but resist acting upon their sexual urges and desires. Although one's sexual orientation is highly unlikely to change, sexual orientation identities are more flexible because they reflect how a person deals cognitively and psychologically with the awareness of their same-sex attractions. Consequently, a comprehensive clinical understanding of a patient's sexuality includes knowledge of all components of their sexual orientation: desire, behavior, and identity.

A *heterosexual identity* refers, in theory, to the subjective experience of those who are primarily aware of erotic attraction to persons of the other sex. As a social construct, heterosexual identity, has not been as well developed or defined as LGB identities. In today's society, unless one has ongoing contact with LGB individuals, a heterosexual identity may not be consciously experienced as anything other than what is expected or "normal." Where a heterosexual developmental outcome is assumed to be the norm, it is assumed that most people have a heterosexual identity unless they either disavow it or proclaim an alternative identity. Consequently, there is no parallel in the development of a heterosexual identity to either the experience of realizing that one is gay, lesbian, or bisexual or the process of revealing that identity to others. These processes are termed *coming out to oneself* and *coming out to others*, respectively. In childhood, most individuals assume that they will become heterosexual adults. Early resistance to accepting one's same-sex attractions and adopting a gay or lesbian identity is, therefore, believed to be a common and nonpathologic feature of the coming out process.

Homosexuality was first introduced as a medical term in the second half of the 19th century to describe erotic desire for persons of the same sex. *Heterosexuality* was coined later to describe erotic desire for persons of the other sex. A third category of sexual orientation, *bisexuality,* was used to describe an attraction to members of both sexes. The terms homosexuality, heterosexuality, and bisexuality are not applied consistently in theoretical, research, or popular discourse. Depending on the context, these terms have been used to refer to a wide range of differing constructs. These include the categories of sexual desire, gender role attributes, forms of sexual behavior, and personal and social identities. In the 19th century, bisexuality referred to a hypothetical bipotentiality of an organism to physiologically develop as either a male or female of its species. Upon discovery that the embryonic precursors of the external human genitalia did not differentiate as male or female until the 12th week of gestation, it was assumed that human beings carried a bisexual potential for psychic development in them as well. Sigmund Freud, among others, working prior to the elucidation of the biologic sexual differentiation of the mammalian brain, took this paradigm one step further and hypothesized that human beings are psychologically bisexual. Many theorists work from an underlying assumption that sexual orientation reflects some unitary quality or essence, rooted perhaps in biology, that transcends cultures and historical periods. Belief in this common essence has been termed *essentialism,* and those who hold this belief are referred to as *essentialists.* Essentialist assumptions have sometimes dismissed or minimized the personal and social meanings of sexual desire and relationships that contribute to sexual identities. The contrasting view that these phenomena are culturally and historically dependent is referred to as *constructionism.* Constructionist assumptions tend to dismiss the role of biology. Although essentialism and constructionism are often viewed as competing schools of thought, that is not necessarily the case. Essentialist theory, in general, deals with sexual orientations, while constructivist theory usually deals with sexual identities. It is certainly possible that individuals throughout history have had sexual orientations as described above, even in cultures where the concept of sexual orientation did not exist and in which sexual orientation had less effect on the individual's identity, or social role and labeling.

In this chapter, *homosexuality* refers to the characteristic of having erotic desire directed toward someone of one's own sex and gender identity and usually of the same birth-assigned sex. Its presence in an individual does not necessarily imply or dictate the concurrent presence or absence of any other characteristics such as heterosexual attractions or gender-typical/atypical interests and behaviors, including mannerisms. It should be further noted that respectful person-first language does not employ sexual orientation descriptors as nouns. Rather than referring to "heterosexuals, bisexuals, and homosexuals," person-first language employs these terms as adjectives (e.g., heterosexual individual, homosexual individual, etc.). When used as an adjective, *homosexual* can also refer to sexual ideation or activity involving members of the same-sex or gender identity.

Similarly*, bisexuality* can refer to an erotic propensity, an individual identity, or a pattern of sexual behaviors. Bisexuality may occur *sequentially* (expressed as an attraction to or relationship with both sexes, albeit at different times in one's life) or *concurrently* (attraction to or relationships with individuals of both sexes at the same time). Some theorize that bisexuality signifies a form of identity diffusion or a transitional state leading toward the development of a more stable heterosexual or gay or lesbian identity. However, some individuals maintain a stable and persistent bisexual identity and pattern of sexual behaviors and/or attractions across time. Limited research suggests that bisexual women are often perceived by nonbisexual people as "over-sexed" while bisexual men are perceived as being unable to accept their homosexuality. Thus, bisexual individuals may experience more social stigma than gay people and may be reluctant to declare themselves. In this chapter, references to bisexuality and bisexual persons are sometimes included because some parallels exist in the experiences of homosexual and bisexual individuals. A fuller discussion of the topic of bisexuality, however, is beyond the scope of this chapter.

In the latter part of the 20th century, the terms *gay, lesbian,* and *bisexual* emerged in popular usage as a way to refer to men and women whose sexual identity, to some degree, consciously acknowledged their sexual attractions to their own or both genders. *Gay* is sometimes also used as a politically inclusive term for both men and women whether they experience homosexual or bisexual attractions. In contrast to the medical term, *homosexual,* which focuses on one aspect of a person's identity, their sexual attractions, as if it were the sum of the person's entire identity, the terms *lesbian* and *gay* have the advantage of not necessarily connoting sexual acts.

In recent years, there has been an increasing proliferation of additional gender categories and simultaneous rejection of the gender binary, a system that recognizes only two (i.e., male and female) genders. Consequently, the term *bisexual,* which implies attraction to only two genders (i.e., male and female), has been joined by a more recent adjective, *pansexual*. This term was coined to indicate a pattern of sexual attraction to other people that is not limited by their sex, sex assigned at birth, current gender identity, or manner of gender expression. Some who do not experience sexual attraction to others may employ the label *asexual* to indicate they are not sexually attracted to others, while some may use this label to indicate that they do not engage in sexual activity with others. Others may describe themselves as *demisexual to* indicate they experience sexual attraction only in the context of an emotional relationship. *Questioning* is sometimes used as an identity label by individuals who are not sure of their sexual orientation. Individuals who are struggling to find the "right" label for their sexual orientation sometimes benefit from learning about *questioning* as an identity label. *Queer* is the preferred identity label of some who are members of either the sexual or gender minority community, or both. While *queer* was once universally considered a slur, it was reclaimed as an empowering label by some sexual and gender minorities through the academic discipline of queer theory and street-level activism. Nevertheless, it continues to be considered pejorative by many members of the gay community—again, it is always helpful to ask.

In much of the early psychologic and psychoanalytic literature, *homosexual* was used as a noun to designate a person with same-sex desire or behavior; however, the use of the term as a noun has decreased in both scientific and popular discourse. For example, recognizing the wide range of sexual identities in those populations at risk of transmitting human immunodeficiency virus (HIV) infection through sexual behavior, the literature on HIV and acquired immunodeficiency syndrome (AIDS) refers to *men who have sex with men* (MSM). MSM do not necessarily think of themselves as gay or bisexual. In some cultures, only a receptive sexual partner is considered gay or homosexual, while an insertive man who also has sex with men and women is not culturally defined as either homosexual or bisexual. Thus, efforts to categorize people on the basis of particular behaviors often come into conflict with both cultural and subjective experiences of the meaning of homosexuality.

Many historical discussions of homosexuality erroneously conflated sexual orientation with *gender identity* and linked homosexual or bisexual orientations with abnormal gender identity. Such theories presumed the cause of homosexual attractions and behaviors to reflect confusion about one's own gender identity, which was then thought to subsequently cause confusion about the sex of individuals to whom one was attracted. However, in contrast to *gender dysphoria,* homosexuality usually entails no desire to transition or to affirm one's gender as being different from that assigned at birth but instead signifies that one's erotic interests are by and large confined to members of one's own sex, gender identity, and gender role. Transgender phenomena are addressed comprehensively in the Gender Identity chapter.

Transvestitism refers to sexual urges and fantasies involving crossdressing. When the behavior is distressing to a patient and brought to the attention of a psychiatrist, it may be diagnosed as *transvestic disorder,* which DSM-5 classifies as a *paraphilic disorder* (refer to Paraphilias section). Crossdressing is strongly linked in the popular imagination with homosexuality. However, in DSM-IV-TR, the diagnosis of *transvestic fetishism* could only be made in heterosexual men as most fetishistic crossdressers are heterosexual men who crossdress in private. These men are often married to women who may or may not know about their crossdressing interests. DSM-5 removed the restriction to heterosexual men, opening the diagnosis to women or gay men who crossdress out of sexual interest. While the change could increase the number of people diagnosed with transvestic disorder, the diagnosis still requires that individuals experience significant distress or impairment because of their behavior and urges. In any event, most gay men and lesbian women do not crossdress. However, there are social venues within gay and lesbian communities that allow for public crossdressing. These may include either socially performative events (gay pride, Carnival, Halloween, or Mardi Gras parades) or crossdressing as a form of paid entertainment (drag shows).

THEORIES

Although heterosexuality is often regarded as nature's default setting—and therefore not requiring any explanation—theories of homosexuality's "causes" abound. One exception can be found in Plato's *Symposium,* which tells a creation myth explaining not only male and female homosexuality but heterosexuality as well. According to this myth, humanity originally consisted of three sexes. Its members were joined in pairs consisting of two men, two women, or a man and a woman (androgyne). To diminish their power and teach them to fear the gods, Zeus divided each pair in half. Thereafter, the split-off aspects were in constant search for their missing halves. Thus, men who were originally one-half of the androgyne seek women and vice versa. Women who seek women and men who seek men were instead part of the original male and female beings.

Although male homosexual behavior played an important and ritualized role in ancient Babylonia and classical Greece, homosexual acts were prohibited in other cultures. In the Abrahamic religions (Judaism, Christianity, and Islam), prohibitions against homosexual behavior as sinful can be found in religious texts. In the Old and New Testaments of the Bible, these include Genesis 19, Leviticus 18:7, 22, Leviticus 20:13, Judges 19, I Kings 22:46, II Kings 23:7, Romans 1:27, I Corinthians 6:9, and I Timothy 1:9–10. Historian John Boswell argued that contemporary intolerance of homosexuality was not an essential factor of Christianity itself but only became a prevailing church attitude in the second millennium ACE. Although Michel Foucault argued that the idea of identifying *a type or a category of person* based on either homosexual behavior or identity is a relatively new cultural phenomenon that coincides with the medicalization of homosexuality during the 19th century, Boswell believed that a category of homosexual individuals, although not entirely equivalent to a modern gay- or lesbian-identified individual, has always existed across time and cultures. Plato's androgyne myth, for example, accounts for the origins of such categories. Foucault and Boswell may each have been right in that recognition of a category of individuals defined by their sexual orientation (as opposed to engaging in homosexual behaviors) has been discontinuously present across history, and that at any given point in history it is recognized by some cultures and religions but not by others. Today, the study of the forms and meanings of homosexual behavior in different cultures and historical periods is a rich field primarily engaged in by scholars of *lesbian and gay studies* and *queer theory.* Nevertheless, the forms of socialization and identity development associated with homosexuality in contemporary Western society are generally considered to be unique. The history of the development of present forms of homosexual identity under the Western influence is the focus of the following review of theoretical perspectives about homosexuality.

History

The contemporary debates about the meaning of homosexuality can be traced to the middle of the 19th century, when European sexologists, including several prominent psychiatrists, began the study of homosexuality from a scientific and medical perspective. Through much of the 20th century, this intellectual enterprise was dominated by a predominance of biologic and psychological, particularly psychoanalytic, theories of homosexuality. Psychiatric theories of the first half of the 20th century, with a few exceptions, regarded homosexuality as either a form of psychopathology or as a developmental arrest. In the latter half of the 20th century, however, theories that characterized homosexuality as a normal variant of human sexuality began to gain ascendance. This view emerged from a wide range of social and scientific perspectives outside medicine and psychiatry and eventually supplanted earlier theories of homosexual pathology and immaturity. This modern *normal variant* view began gaining influence around the time of the publication of the two Kinsey volumes on male and female sexuality—in 1948 and 1953, respectively—and culminated in the APA's removal of homosexuality from its list of mental disorders, the DSM, in 1973. This action later prompted WHO to remove homosexuality *per se* from ICD-10 in 1990 and to later remove all references to sexual orientation from ICD-11 in 2019. Consequently, the normal variant model is accepted by today's mental health mainstream.

Medicalization of Homosexuality: From Morality to Pathology

19TH- AND 20TH-CENTURY BIOLOGIC VIEWS. The evolution of today's conceptualizations of homosexuality is often tracked from the mid-19th century. In 1864, in response to Bavaria's Paragraph 175, which criminalized male (but not female) homosexual acts, German lawyer and activist Karl Ulrichs began publishing treatises that criticized the law. Ulrichs theorized that some women were born with a man's spirit trapped in their bodies (*Urningins*), and some men were born with a woman's spirit trapped in theirs (*Urnings*). Although he said these people constituted a "third sex," the concept drew on a binary approach to gender that presumed an attraction to men is a feminine attribute and that an attraction to women is a masculine one.

In 1869, a Hungarian writer, Károli Mária Kertbeny, who also wrote critically about laws criminalizing same-sex behavior (*sodomy laws*), first coined the terms *homosexual* and *homosexuality.* The influential psychiatrist, Richard von Krafft-Ebing, later adopted and popularized the terms in his 1886 classic *Psychopathia Sexualis.*

Krafft-Ebing and the psychiatrist Carl Westphal adopted many of Ulrich's ideas; however, the former two deemed unnatural (*theories of pathology*) the very same traits that the latter had described as normal. Magnus Hirschfeld, a German physician and sexual emancipator was an openly homosexual psychiatrist who also believed there was a biologic basis for homosexuality. Although he considered homosexuality to be one of several "intermediate sexual types," presumed to have a number of different biologic etiologies, Hirschfeld, the standard-bearer of *third sex theory in his time,* nevertheless asserted that the condition was natural (*theory of normal variation*). Similarly, the English sex reformer Havelock Ellis thought of homosexuality as a biologic variation. And although he attributed it to "imperfect sexual differentiation," he nevertheless considered homosexuality to be nonpathologic since it did not cause any illness in the affected individual. Other biologic bases for homosexuality began to be examined during this period. These included studies of anatomical structures in the brains and nerve structures in the rectums of homosexual men. Endocrinologic hypotheses led to experiments in which the supposedly atrophied or abnormal testicles of homosexual men were removed and replaced with what were believed to be the normal testicles of heterosexual men. However, these experiments did not make homosexual men heterosexual.

Early biologic theories, with their emphasis on heredity, endocrinologic influences, and anatomical or structural differences between homosexual and heterosexual persons, heralded many of the recent efforts to find a biologic basis for homosexuality, some of which were interpreted as suggesting that homosexuality is biologically determined and, therefore, not derivative of childhood experiences or indicative of psychopathology. Biologic theories, however, also provided a rationalization for eugenic efforts in Germany to eradicate homosexual persons. As recently as the 1970s, East German surgeons unsuccessfully tried to eliminate homosexuality in men by operating on the hypothalamus where the “cause” of homosexuality was presumed to lie. Throughout the 20th century, interest in the origins of sexual orientation focused almost exclusively on men, a trend less evident today.

PSYCHOANALYTIC APPROACHES. Freud did not view homosexuality as a sign of illness, by which he meant a symptom arising from psychic conflict. Instead, he saw homosexuality as the unconflicted expression of an innate instinct. Although his conjectures were based on clinical observations rather than objective studies, he noted that homosexuality could occur in individuals who had no other signs of deviation and no impairment in their functioning. Freud believed in *constitutional bisexuality* that every individual had a certain component of *masculine* (active) as well as *feminine* (passive) *tendencies.* A homosexual tendency did not necessarily imply a homosexual behavior. Although he viewed bisexual tendencies as universal, Freud believed some people were constitutionally endowed with more of one tendency than the other. He believed life experiences, particularly traumatic ones (environmental factors), could have an impact on the development and expression of one’s innate instincts (biologic factors). Under normal and nontraumatic circumstances, the component instincts that determine the sex of one’s final object choice should be consistent with one’s anatomical sex. That is to say, an anatomic male should ideally express the masculine component instinct and obtain sexual satisfaction from women. However, Freud also conjectured that even adults who are ostensibly heterosexual individuals retain the homosexual component, albeit in sublimated form. For Freud, adult, nonsublimated homosexuality represented an arrest in development on the road from the instinctual bisexuality of childhood to mature heterosexuality. His *theory of psychic immaturity,* that is, a developmental arrest to account for adult homosexuality, comprised an alternative category to religious sin, medical theories of pathology, or normal variant third-sex theories. By maintaining that some degree homosexuality, at least developmentally, could be a normal part of everyone's experience, Freud's conjectures allowed for the possibility that the adult homosexual person might sufficiently mature and, if sufficiently motivated, become heterosexual. However, late in his life, Freud doubted the possibility of changing a homosexual orientation to a heterosexual one.

After Freud's death, Sandor Rado's theories came to hold greater sway on psychoanalytic theorizing about homosexuality. In the 1940s, Rado argued that the theory of bisexuality was based on a faulty analogy with anatomical bisexuality. That is, underlying Freud's theory was a 19th-century belief in embryonic hermaphroditism, the hypothesis that the potential to become an anatomical man or a woman was present in every embryo. Rado claimed this theory had been disproved, which led to his claim that heterosexuality is the only nonpathologic outcome of human sexual development. He viewed homosexuality as an illness, specifically a phobic avoidance of the other sex caused by parental prohibitions against childhood sexuality. Almost all of the mid-20th century psychoanalytic theorists who pathologized homosexuality followed Rado's theory in one form or another. The psychoanalytic community's shift from Freud's model of immaturity (homosexuality as a normal developmental step toward adult heterosexuality) to Rado's model of pathology (homosexuality as a sign of development gone awry) led some analysts to claim they could "cure" homosexuality.

The work of psychoanalyst Irving Bieber and his associates was particularly influential in its portrayal of a pathogenic family type—a detached and rejecting father and a close-binding and domineering mother—that presumably led to homosexuality in the 106 adult homosexual men they studied. This theory of familial etiology, however, has not found support in the research of larger, nonpatient gay male populations. Although about 70% of their subjects dropped out during treatment, Bieber and his colleagues claimed a 27% cure rate among 29 of the 32 men who remained in the study. The Bieber study was criticized for its methodology

—it was not peer-reviewed—and the authors were unable to provide any long-term follow-up data on their subjects or produce any patients to support their claims of change. Finally, while some discussion of the etiology of female homosexuality existed in the early psychoanalytic literature, the primary emphasis in psychoanalysis, as in the biologic sciences, was on male homosexuality; often, presentations of homosexuality in women were simply treated as gender-reversed images of those for male homosexuality.

EARLY THEORETICAL ASSUMPTIONS. Nineteenth and early 20th-century theories of homosexuality, be they biologic (e.g., neurologic or endocrinologic), developmental, or psychoanalytic, largely relied on a dichotomous model of categories: Male/female, masculine/feminine, and heterosexual/homosexual. Whether the theorist believed homosexuality to be a normal variant, a form of pathology, or immaturity, the theory usually relied on the assumption that the wide range of human sexuality could be reduced to the two-component parts of male and female and that some intrinsic quality of one gender had made its way into a person of another gender. In addition, scientific and medical studies served to remove the responsibility of defining homosexuality from the realms of morality and religion and secured that task within science and medicine. In doing so, science and medicine created a category of person, “the homosexual,” in contrast to earlier moral and religious beliefs that homosexuality was a type of sinful sexual behavior that could be engaged in by anyone, rather than an erotic response pattern directed toward members of one’s sex. Although science and medicine perpetuated the social stigma of homosexuality, taking it out of the realm of sin and immorality into the realm of pathology and immaturity, these developments would also eventually set the stage for the transition toward normalizing homosexuality that began to take shape in the middle of the 20th century.

Normalization of Homosexuality: From Diagnosis to Normality

INFLUENCE OF RESEARCH FINDINGS FROM SEXOLOGY, CROSS-CULTURAL, ANIMAL, AND PSYCHOLOGICAL STUDIES. A major factor in the shift away from pathologizing theories about homosexuality was the work of sex researchers. Unlike psychiatrists and psychoanalysts, who based their theories on clinical work with people seeking treatment in their offices or on evaluations of prison populations, sex researchers sampled larger, nonpatient populations. Thus, the publication of two studies on male and female sexuality by Alfred Kinsey and his colleagues, in 1948 and 1953, respectively, proved to be a scientific and cultural watershed. Hundreds of thousands of copies were sold of the two reports, and were translated into many languages. Although normal variant theories of homosexuality had been around for almost a century, at the time of its publication, Kinsey's work signaled the beginning of a cultural shift away from viewing homosexuality as pathology toward viewing it as a normal variant of sexual desire and behavior. Despite his studies' methodologic flaws, Kinsey's finding of a widespread presence of same-sex feelings and behaviors among his samples of several thousand American men and women changed the general impression that homosexuality was a rare and pathologic phenomenon. His homosexuality/heterosexuality scale, which conceptualized sexual orientation on a continuum, expanded on the binary model used by earlier theorists. As Kinsey put it in his 1948 report, "The world is not to be divided into sheep and goats. Not all things are black, nor all things white. It is a fundamental of taxonomy that nature rarely deals with discrete categories. Only the human mind invents categories and tries to force facts into separated pigeon-holes. The living world is a continuum in each and every one of its aspects."

Cleland Ford and Frank Beach's work, published in 1951, found homosexual behavior to be common across cultures and documented its existence in almost all nonhuman primate species. The interpretation of these findings supported the notion that homosexuality was both natural (as opposed to a traditional view that it was caused by civilized decadence) and widespread. In 1957, psychologist Evelyn Hooker published a ground-breaking study comparing projective test results from 30 nonpatient homosexual men with those of 30 nonpatient heterosexual men. Her study found that experienced judges, unaware of whose test results they were interpreting, could not distinguish between the two groups. Again, the medical and psychiatric literature of that time, which regarded homosexuality as pathologic, was mostly based on evaluations of individuals troubled about their sexuality. Hooker's study of *nonpatient subjects* was a serious challenge to the then-prevailing psychiatric and psychoanalytic belief that homosexuality was always associated with mental illness or serious psychopathology. One of the significant impacts of Hooker's finding was to draw attention to the a priori assumption of many clinical papers that homosexuality was itself pathologic. In the

1960s, psychiatrists like Judd Marmor—a psychoanalyst and future president of the APA—Robert Stoller (also a psychoanalyst) and Richard Green gave serious consideration to the nonpsychiatric perspectives offered in these newer research findings. Another psychiatric/psychoanalytic dissenter was Thomas Szasz, who criticized mental health professionals in general for labeling many unconventional behaviors as signs of illness. Rather than practicing medicine, Szasz accused his fellow psychiatrists of using diagnoses as a way to increase their own power and influence.

DECLASSIFICATION BY THE AMERICAN PSYCHIATRIC ASSOCIATION. Homosexuality had been officially classified as a mental disorder in APA's first edition of the DSM (DSM-I) in 1952. There it was designated as a type of "sociopathic personality disturbance." Classifying homosexuality as a mental illness was not controversial at the time of the DSM-I's publication; societal attitudes of that time coincided with prevailing medical views that homosexuality was an aberration. In 1968, the revised DSM-II still listed homosexuality as a "sexual deviation," but sexual deviations were no longer categorized as a sociopathic personality disturbance.

The DSM's 1968 revision (DSM-II) coincided with a time of great social foment in the United States. In addition to anti-Vietnam War activity, Black civil rights protests, and emerging feminist voices, gay rights activism also gained public notice. Gay activism coalesced around the 1969 Stonewall riots in New York City. Efforts by police to raid and shut down a gay bar (The Stonewall), a routine police activity of the time, led to 3 days of rioting in Greenwich Village. Having fought off police and government successfully, the gay rights movement was prepared to challenge psychiatric authority as well. This led to increasingly vocal opposition to psychiatry's classification of homosexuality as a mental disorder. Before that time, many homophile organizations, both in the United States and abroad, had accepted the medical view of homosexuality as a mental disorder. Accepting the view of homosexuality as a disease meant treating it as a disability, a category intended to replace moral and religious judgments with scientific, objective, and humane attitudes. However, in most instances, medical and psychiatric portrayals of homosexuality were as problematic as the religious views they supplanted. For example, a homosexual individual could be denied the right to immigrate to the United States on the grounds that the person suffered from a mental disorder. Gay men and lesbian women were discharged from the military as medically unfit. To gay and lesbian activists of that period, the psychiatric designation of homosexuality as a mental disorder had exacerbated antihomosexual societal prejudices rather than ameliorated them. These activists found a receptive audience among an increasing number of psychiatrists familiar with the nonpsychiatric research findings showing homosexuality occurred in large numbers of people, in persons who demonstrated normal psychological adjustment, and across cultures.

Gay activists chose to confront APA about its position on homosexuality —they disrupted APA's annual meetings in 1970 and 1971. In response to these protests, APA's leadership took several steps. First, they permitted two educational panels at the APA's 1971 and 1972 meetings. The 1971 panel, titled "Lifestyles of Non-Patient Homosexuals," featured nonpatient gay activists explaining to their psychiatric audience the stigma caused by the "homosexuality" diagnosis. At the 1972 meeting, the activists were on another panel, "Psychiatry: Friend or Foe to Homosexuals: A Dialogue." The latter panel presented the perspectives of the activists, Judd Marmor, and psychiatrist, John Fryer, M.D., who appeared as "Dr. H Anonymous," disguising his true identity from the audience with a rubber mask, a fright wig, and an oversized tuxedo. He spoke of the discrimination gay psychiatrists faced in their own profession, telling his psychiatric audience:

> *As psychiatrists who are homosexual, we must know our place and what we must do to be successful. If our goal is academic appointment, a level of earning capacity equal to our fellows, or admission to a psychoanalytic institute, we must make certain that no one in a position of power is aware of our sexual orientation or gender identity. Much like the black man with the light skin who chooses to live as a white man, we cannot be seen with our real friends—our real homosexual family—lest our secret be known and our dooms sealed.* (John Fryer Papers (Collection 3465), Historical Society of Pennsylvania. Finding aid. Accessed May 3, 2023. http://digitalhistory.hsp.org/pafrm/doc/speech-dr-henry-anonymous-john-fryer-american-psychiatric-association-125th-annual-meeting.)

The second step taken by APA, in addition to these public panels, was to embark upon an internal process of studying the scientific question of whether homosexuality should be considered a psychiatric disorder. APA's Nomenclature Committee was the scientific body charged with addressing this issue. The Committee members reviewed the psychiatric and psychoanalytic literature on the subject as well as the sexology literature. The latter, a subject not usually taught in psychiatric training programs at that time, was unfamiliar to most practicing psychiatrists. Following their study of the issue, which included interviews with psychiatrists who favored and objected to making any changes, the Nomenclature

Committee recommended removing homosexuality per se from the DSM. The proposal was approved by the APA's Council on Research and Development, its Reference Committee, and by the Assembly of District Branches (now known as the APA Assembly) before being accepted by APA's Board of Trustees in December 1973. This marked the end of the classification of homosexuality per se as an illness. Other major mental health professional organizations, including the American Psychological Association and the National Association of Social Workers, soon endorsed the APA action. The decision to declassify homosexuality was accompanied by passage and issuing of a position statement by the APA that supported the protection of the civil rights of homosexual persons and that read:

> *Whereas homosexuality in and of itself implies no impairment in judgment, stability, reliability, or vocational capabilities, therefore, be it resolved that the American Psychiatric Association deplores all public and private discrimination against homosexuals in such areas as employment, housing, public accommodations, and licensing, and declares that no burden of proof of such judgment, capacity, or reliability shall be placed on homosexuals greater than that imposed on any other persons. Further, the APA supports and urges the enactment of civil rights legislation at local, state, and federal levels that would insure homosexual citizens the same protections now guaranteed to others. Further, the APA supports and urges the repeal of all legislation making criminal offenses of sexual acts performed by consenting adults in private.* (Reproduced with permission from American Psychiatric Association. *American Psychiatric Association Position Statement on Civil Rights of Homosexual Persons*. American Psychiatric Association; 1973.)

Some psychiatrists, primarily psychoanalysts, who continued to adhere to pathologizing views of homosexuality, criticized the Board of Trustees and challenged their action by petitioning the organization to hold a referendum in which the entire APA membership could vote. The Board of Trustee's decision to remove homosexuality from the DSM was upheld by a 58% majority of voting APA members.

The original scientific and clinical rationale for removing homosexuality from the DSM was based, in part, on a new formulation of the definition of a mental disorder by the Nomenclature Sub-Committee's Chair, Robert Spitzer M.D. In order to be classified as a disorder, a condition had to meet the criteria of either an experience of subjective distress or of a generalized, objective impairment in social effectiveness or functioning resulting from the condition itself. Neither of these criteria applied to gay and lesbian individuals who were satisfied with their sexual orientation and who did not demonstrate impaired functioning. In recognition of the opposition to the diagnostic change, however, the APA did not fully embrace a normal variant model of homosexuality; instead, it made a compromise. The diagnosis of *homosexuality* in the original text of DSM-II was replaced by *sexual orientation disturbance* (SOD) in its seventh printing in 1974. As a result, individuals comfortable with their homosexuality were no longer considered mentally ill. According to SOD criteria, only those who were “bothered by,” “in conflict with,” or “wished to change” their homosexuality had a mental disorder.

The diagnostic category of SOD had two significant conceptual problems. First, the diagnosis could also apply to heterosexuals, a solution to APA’s internal debate that did not concur with clinical reality. There were no reported cases of unhappy heterosexual individuals seeking psychiatric treatment to become homosexual. This problem of diagnostic over-inclusiveness was resolved in the 1980s DSM-III, where SOD was replaced by *ego-dystonic homosexuality* (EDH). The name change, however, did not resolve a thornier conceptual issue, which was that of making patients’ subjective experiences of their own homosexuality *the determining factor* in labeling their homosexual feelings as an illness. To rely on patient subjectivity as the major determining factor was now incongruous with the new evidence-based approach that psychiatry had embraced with DSM-III. This ultimately led, in 1987, to EDH being removed from the revised DSM-III-R. In 1990, the WHO followed suit and removed homosexuality from the 10th revision of the ICD (ICD-10), replacing it with a diagnosis that resembled SOD: ego-dystonic sexual orientation. This diagnosis was removed from ICD-11 in 2019.

For two decades after the 1973 APA decision, the meetings and publications of the APsaA were among the few American mental health forums where pathologic views of homosexuality continued to be expressed. Eventually, however, normal variant views of homosexuality prevailed in the APsaA as well. In 1991, the organization issued a nondiscrimination statement to allow training of gay and lesbian psychoanalytic candidates and the promotion of qualified gay and lesbian individuals to the position of training and supervising analyst. In 1997, APsaA became the first major mental health organization to support marriage equality. In 2000, APsaA took a position opposing sexual conversion therapy. However, psychoanalytic views that pathologized homosexuality nevertheless could still be found in the international psychoanalytic community. Then, in 2002, APsaA's influence in the International Psychoanalytical Association (IPA) led the latter to issue a nondiscrimination statement allowing for the selection of openly gay and lesbian candidates and the promotion of gay and lesbian faculty. In 2019, coinciding with the 50th anniversary of the Stonewall uprising, APsaA President Lee Jaffe issued a public apology to the lesbian, gay, bisexual, and transgender (LGBT) community for the organization's role in perpetuating stigma and discrimination.

In 2019, the WHO Assembly approved a recommendation of its Working Group on Sexual Health and Sexual Disorders that recommended the removal of the F66 diagnoses, including ego-dystonic sexual orientation, from ICD-11. The Working Group, reviewing the evidence published since 1990, found no evidence that these diagnoses were clinically useful as they did not contribute to health service delivery or treatment selection nor provide essential information for public health surveillance.

All of these actions represent definitive acknowledgment by the psychiatric, psychoanalytic, medical, and mental health professions that homosexuality, in itself, is not a mental disorder. Not only does this change in the mental health professions' view of homosexuality represent a wider acceptance of an affirming and more scientific view of homosexuality, but it also symbolizes a dramatic conceptual shift in the cultural meaning and significance of homosexual behavior, particularly within, but not entirely limited to Western culture.

PREVALENCE

One must use caution when interpreting studies that address the prevalence of homosexuality in a population. First, one must consider the survey methods: What population did the survey aim to assess? Was a random sample of this population ascertained, and was the sample large enough to provide statistically meaningful results? One must clearly identify which aspects of sexual orientation were assessed (e.g., sexual desire for men, women, or both or neither; sexual activity with men women, both or neither; sexual identity [heterosexual/straight, homosexual/gay/lesbian, bisexual, pansexual, asexual, other]). Ideally, surveys should also assess the gender of participants by querying both their sex assigned at birth (e.g., what sex or gender was on your initial birth certificate [male, female, other–specify]) as well as how they identify their gender currently (male, female, transgender man, transgender woman, other, etc.). Additionally, one must determine whether surveys reflect the proportion of respondents who have ever experienced same-sex desire, who have ever engaged in same-sex behavior, or who have identified themselves as homosexual at any time in their lives, within a restricted period of time, at a particular stage of their lives, or in a stable and ongoing pattern.

Beyond the issues of survey design, the stigma associated with homosexuality may interfere with full disclosure. The impact of stigma on survey results may vary depending on the survey method. Although face-to-face interviews are generally considered preferable, logistical issues may limit the sample size or the geographic region(s) surveyed. Surveys based on random telephone numbers may achieve large representative nationwide samples but may result in underreporting of homosexuality if the subjects do not have privacy at the time of their telephone interview.

Regardless of the survey method employed, persons who are not accepting of or open about their sexual orientation are less likely to respond fully or accurately to questions about their sexual behavior or identity. Thus, even large-scale random surveys are more likely to result in underestimates rather than overestimates of homosexual phenomena. Here, the history of assessing the prevalence of homosexuality, primarily in the United States, is reviewed chronologically.

The Kinsey Survey of Male Homosexuality

The 1948 Kinsey study of male sexuality, based on a sample of over 5,000 men between the ages of 16 and 55 years, concluded that 4% of the men were exclusively homosexual throughout their lives after adolescence, 50% were exclusively heterosexual, and 46% were somewhere in between. The report also concluded 10% of males are “more or less exclusively homosexual for at least 3 years between the ages of 16 and 55.” The latter conclusion eventually became the basis of the common misperception that 10% of the population is homosexual.

The Kinsey study has subsequently been criticized for its sampling errors, including an overrepresentation of men with histories of incarceration, which are believed to have led to inflated estimates of the extent of homosexual and bisexual behavior. However, Paul Gebhard, Kinsey’s successor as director of the Kinsey Institute for Sex Research, dedicated years to culling purported contaminants from Kinsey’s data and concluded that his figures were off by no more than a few percentage points. In addition, Kinsey's numbers are not that different from recent large-scale surveys employing modern sampling methods. While absent in early studies, recent studies have included women.

Later Surveys

A large-scale study of sexuality in the United States published in 1994 by Edward Laumann and colleagues was long regarded as providing the most reliable estimates of the prevalence of homosexuality in the United States. This study inquired about individual desire, behavior, and identity and obtained a carefully stratified representative sampling of the general population. This study, based on a total sample of 3,159 men and 1,749 women, found that 2.7% of the men and 1.3% of the women had participated in same-sex sexual behavior during the preceding year, and 4.9% of the men and 4.1% of the women had done so since age 18; 7.7% of the men and 7.5% of the women reported having experienced sexual desire for someone of the same-sex, and 2.8% of the men and 1.4% of the women reported a homosexual or bisexual identity. These figures varied considerably across groups based on age, marital status, education, religion, race, and place of residence. Several surveys done over the past 20 years in Canada, Australia, and Europe have produced similar results.

A 2011 report by the Institute of Medicine called attention to marked disparities in sexual and gender minority populations in both physical and mental health. It called for all federally funded national health surveys to include queries regarding sexual orientation and gender identity so that health disparities could be characterized and addressed in different sexual and gender minority populations. Currently, 10 national data systems have begun to collect such data. Of these, two, the National Survey of Drug Use and Health (NSDUH) and the National Survey of Family Growth (NSFG), have assessed three domains of sexual orientation (attraction, behavior, and identity) in adults ages 18 to 44 and the Population Assessment of Tobacco and Health (PATH) has assessed these domains in adolescents ages 14 to 17 (Table 21.2–1). For men (ages 18 to 44), these surveys found that over 2.3% to 2.8% endorsed being mostly or exclusively attracted to men, while approximately 2% identified as gay, with approximately another 2% identifying as bisexual. For women (ages 18 to 44), 1.6% to 2.5% reported being mostly or only being attracted to the same gender, with 1.6% to 2.5% reporting being attracted to both genders, while 1.3% to 1.5% identified as lesbian or gay.

Table 21.2–1.
Sexual Attraction and Identity Reported by Adults and Adolescents in U.S. National Surveys

Sexual Attraction Reported by Adults

Males	**NSDUH**	**NSFG**
Only/mostly to other gender	93.8	95.3
Equally to both genders	1.1	0.8
Only/mostly to same gender	2.8	2.3
Unsure	1.3	0.7
Females		
Only/mostly to other gender	90.5	93.4
Equally to both genders	4.3	3.2
Only/mostly to same gender	2.5	1.6
Unsure	1.4	1.2

Sexual Identity Reported by Adults

Males	**NSDUH**	**NSFG**
Heterosexual	95.1	95.0
Gay	2.2	1.9
Bisexual	1.4	2.0
Don’t know	0.4	[a]
Refused to answer	0.8	[a]
No data/missing response	0.1	[a]
Females		
Heterosexual	92.9	92.2
Gay/Lesbian	1.5	1.3
Bisexual	3.5	5.5
Don’t know	0.8	[a]
Refused	1.2	[a]
No data/missing data	0.1	[a]

Attraction & Identity Reported by Adolescents in PATH Survey

Attraction	**Males**	**Females**

Other sex only	85.6	64.8
Mostly other sex	5.1	13.8
Equally to both	2.0	8.2
Mostly same sex	0.9	2.0
Only same sex	1.1	1.2
No sexual attraction	5.2	10.0
Identity	**Males**	**Females**
Straight	94.6	84.0
Lesbian/Gay	1.3	1.9
Bisexual	2.7	9.8
Something else	1.5	4.3

All data are in percentage.

NSDUH, National Survey on Drug Use and Health (conducted 2015; ages 18–44; *N* = 68,053).

NSFG, National Survey of Family Growth (conducted 2011–2013; ages 18–44; *N* = 10,416).

PATH, Population Assessment of Tobacco and Health Survey (conducted 2015–2016; ages 14–17; *N*= 7,222).

[a]Low precision estimate.

A report published by Rahman and colleagues in 2020 examined the prevalence of self-reported sexual identity and sexual attractions in 28 nations using data from 191,088 participants from a 2005 BBC Internet Survey. Sexual identity was reported categorically as heterosexual, gay/lesbian, or bisexual, and sexual attractions were reported using separate 7-point scales to indicate the degree of attraction to men and to women. Across nations, rates of endorsing a heterosexual identity were essentially the same for men (90.0%) and women (90.7%); however, a significantly greater proportion of men (4.9%) compared to women (2.1%) endorsed a homosexual identity ($P < .001$). The proportion of participants who endorsed a heterosexual identity was significantly ($P < .001$) higher than the proportion who endorsed being not predominately attracted to the same-sex (82.6% and 66.2% for men and women, respectively). Thus, participants who labeled themselves as “heterosexual” included a substantial number of men and women who also endorsed significant attraction to their own sex.

These later studies do not support the aforementioned popular belief that Kinsey's study showed that 10% of the population is gay. In the 12 largest U.S. cities, however, the number of gay and lesbian persons does approach the 10% figure, perhaps reflecting their migration to areas with greater tolerance for sexual diversity or sizable LGB communities. Yet, the 10% figure in the Rahman study for those endorsing something other than a heterosexual identity is similar to the 10% figure from the Kinsey study for men who reported being "more or less exclusively homosexual for at least three years between the ages of 16 and 55."

Given the limitations in existing studies, it is impossible to determine definitively the number of persons who have experienced same-sex attraction, have engaged in same-sex behavior, or identity as LGB or other sexual minority; however recent large-scale studies employing modern survey methods provide similar results.

Historically, there has been a political dimension surrounding the issue of homosexuality's prevalence in the population. Proponents and opponents of gay rights have attempted to respectively exaggerate or diminish the importance of the gay and lesbian presence in the population at large. Although the exact numbers and proportions remain somewhat elusive, it is nevertheless clear that a larger proportion of persons report same-sex desire than report same-sex behavior, and more report engaging in same-sex behavior than report a homosexual or bisexual identity. For example, a 2006 study of men in New York City found 12.4% reported having had sex only with men during the previous year; however, the majority (8.9%) identified as "straight," with only 3.3% identifying as gay and 0.2% identifying as bisexual. For the clinician, it is important to understand that prevalence is dependent on which component of homosexuality and which social or demographic groups are being considered. The validity of estimates of the extent of homosexuality in a given population is likely to be influenced by factors such as the degree of social repression of homosexuality and the cultural meaning of same-sex desire, behavior, and identity. Importantly, with respect to sexually transmitted infections, including HIV, sexual behavior is the risk factor and not sexual identity; therefore, questions to assess risk should address behaviors, not identity.

ORIGINS OF HOMOSEXUALITY

Historically, most research has been done from a heteronormative perspective that treats heterosexuality as normal and therefore not in need of explanation, whereas homosexuality has been viewed as an abnormality to be explained. Consequently, much research has focused on homosexuality in particular rather than on sexual orientation in general, and, until recently, often with the aim of elucidating the origins of homosexuality in order to inform efforts aimed at preventing or “curing” it. Four areas in which research on the origins of homosexuality has focused are biology, cross-cultural studies, psychological development, and the acquisition of gay and lesbian identities.

Biologic Studies

Since the emergence of the concept of sexual orientation in Western medical discourse, there has been a debate as to whether it is determined or primarily influenced by biologic as opposed to psychosocial factors. In recent years, most scholars have suggested that it emerges from an interaction between both sets of factors. The role of biology often enters into sociopolitical debates, sometimes referred to as culture wars, regarding whether or not homosexuality is mutable (perhaps even a chosen lifestyle) and whether gay people should be encouraged to change or be granted civil protections against discrimination. Weaknesses in the evidence base for a biologic contribution to sexual orientation are sometimes employed to support arguments for conversion therapies or discriminatory policies. As shown below, however, even behaviors acquired through experience can be immutable. Furthermore, biologic evidence is not needed to demonstrate that homosexuality is impervious to change. That is clearly evident in the psychological literature reporting the ineffectiveness of multiple forms of therapies designed to change it. While sexual behaviors and sexual orientation identities may shift in some individuals, few if any of even the most highly motivated have changed their homosexual orientation despite subjecting themselves to painful aversion therapies or investing emotional and financial resources in years of psychoanalysis or reparative therapies. Rather than issues of choice, biologic determinism, and immutability, the arguments for equal rights and civil protections for homosexual and bisexual persons, like those for religious and racial minorities, are better framed in terms of human rights, justice, privacy, and liberty.

Before reviewing the biologic research into sexual orientation, this section begins by describing three basic models for conceptualizing the possible contributions of biologic factors and their interactions with psychological and social factors.

Biologic Models to Explain Homosexuality

MODEL OF PERMISSIVE BIOLOGIC EFFECTS. In this model, biology plays a permissive role by providing the neural machinery through which sexual orientation is inscribed by formative experience. A permissive role could also include delimiting the developmental stage during which the relevant formative experiences must occur. For example, some songbirds must learn their species' songs by hearing them during a restricted period of early development. While the song is clearly acquired through experience, biology determines the sensitive period during which that experience must occur. Once a particular song has been acquired, that will be the bird's song for life; it will not be able to unlearn that song or acquire another. This is not meant to imply that sexual orientation might be acquired by simple mimicry. Instead, it shows that phenomena acquired through experience may, nonetheless, be immutable and, therefore, militates against the widespread notion that sexual orientation must be innate since it is impervious to change.

MODEL OF DIRECT BIOLOGIC EFFECTS. In this model, the underlying premise for most biologic research regarding sexual orientation, the actions of biologic factors such as genes and hormones would directly influence the organization or activity of brain circuits that mediate sexual orientation. The brain is viewed as possessing an intrinsic (i.e., constitutional) sexual orientation or predisposition, the expression of which could nonetheless be subsequently modified by experience.

MODEL OF INDIRECT BIOLOGIC EFFECTS. This model addresses the contribution of individual differences, some of which may be constitutionally influenced. In this model, biologic factors influence sexual orientation only indirectly as the more direct or immediate action of biologic factors is upon temperament or other personality traits. From birth, these personality or temperamental traits influence how an individual experiences, interacts with, and modifies the environment. This would include how an individual participates in shaping the relationships and experiences thought by some to influence the development of sexual orientation. Although similar to the model of permissive biologic effects, the model of indirect biologic effects goes further and suggests that the relevant formative experiences, including those that are subjectively experienced, may, themselves, be strongly affected by biologically influenced personality variables.

The existing biologic data relevant to the underpinnings of sexual orientation are equally compatible with both the direct and indirect models. The distinction between these models can be appreciated in their differing interpretations of three of the more robust findings in the sexual orientation literature as reviewed by William Byne and Bruce Parsons. The first of these findings is that the propensity to engage in rough-and-tumble play during the juvenile period appears to be influenced by prenatal exposure to androgenic (i.e., “male”) hormones. Second, compared to heterosexual men, more, but not all, homosexual men recall less childhood interest in competitive rough-and-tumble play. Third, compared to heterosexual men, homosexual men are more likely to recall their fathers as having been distant or rejecting.

In the direct model interpretation, the aversion to rough-and-tumble play represents the childhood expression of a brain that has been prewired for homosexuality. This was the position of Richard Isay, a psychoanalyst who suggested that biologic factors wire the brain for sexual orientation and consequently reverse the polarity of the Freudian Oedipus complex. According to this model, in addition to shunning rough-and-tumble play, prehomosexual boys are erotically interested in their fathers during the oedipal period. Fathers might recoil from their prehomosexual sons’ gender nonconformity or sexual inclinations. Even if the father did not recoil, Isay speculated that in adulthood, gay men might nevertheless recall their fathers as having been cold or distant in order to avoid conscious awareness of their earlier sexual attractions to them.

Alternatively, an indirect model interpretation postulates that a biologically influenced aversion to rough-and-tumble play does not necessarily imply prewiring for homosexuality. Instead, such an aversion becomes a potent factor predisposing to homosexual development in particular environments—perhaps where this behavior is stigmatized as “sissy” behavior and, therefore, causes the boy to see himself as different from his father and male peers. In this scenario, the father's withdrawal from his son would contribute to, rather than result from, his homosexuality. Significantly, an aversion to rough-and-tumble play would arguably have different consequences in environments in which such behavior is acceptable, perhaps making no contribution to sexual orientation at all. This example does not suggest that a distant or rejecting father (whether real or projected) could be a feature of all pathways to male homosexuality. Based on the indirect model, one might conjecture how any number of biologically influenced personality variants could influence sexual orientation. Theoretically, a given variant might predispose to homosexuality in one environment and to heterosexuality in another while making no contribution to sexual orientation in environments in which the variant is perceived to have no valence with respect to perceptions of gender-appropriate behavior.

Neuroendocrine Research. Historically, much biologic research has begun with the premise that the constitution of gay men and lesbian women reflects some intermediary state between that of their male and female heterosexual counterparts. This assumption led to investigations of various attributes for evidence of biologic sexual atypicality in gay men and lesbian women, whether in genes, chromosomes, hormones, hormone receptors, or brain structures. From the 1950s into the 1970s, considerable research examined the endocrine system for atypical levels of the so-called sex hormones in gay men and lesbian women. An overwhelming majority of such studies failed to demonstrate a significant correlation between sexual orientation and adult hormone levels. In fact, androgens, frequently referred to as "male hormones," although they are present in both sexes, have been found to increase sexual desire in both men and women and yet have no effect on sexual orientation. Moreover, sexual orientation does not change in adults when hormone levels are altered by gonadal malignancies, trauma, or surgical removal. Currently, however, there remains much speculation about the potential role of prenatal exposure to androgens and other hormones derived from them. Variations in exposure could be mediated by variations in hormone syntheses, transport mechanisms, blood or brain levels, enzymatic degradation or modification, or variations in hormone receptors or epigenetic modifications of DNA that affect any of the foregoing.

THE PRENATAL HORMONAL HYPOTHESIS. This hypothesis posits that (1) the brains of heterosexual men and women differ from each other both structurally and functionally; (2) these sex differences in the brain result, at least in part, from early, perhaps prenatal influences on brain development; and (3) some of these hormonally influenced differences determine whether one is sexually attracted to men and/or to women. This perspective, therefore, views sexual orientation as a derivative of a hormonally mediated developmental process leading to sexual differentiation of the brain. Consequently, the brains of homosexual individuals are expected to exhibit neurobehavioral characteristics considered to be more typical of the other sex. This supposition has sometimes been referred to as the *intersex hypothesis* of homosexuality, that is, that the brain of homosexual and bisexual individuals is intermediate in some ways between a prototypical male and female brain.

The prenatal hormonal hypothesis draws extensively on numerous studies and observations of rodents, in which the balance between male and female patterns of mating behaviors is strongly influenced by the amount and timing of early androgen exposure. The period of maximal sensitivity to these organizing effects of androgen varies in different species. The rat has been employed extensively in such research because its period of brain sexual differentiation extends into the early postnatal period (which corresponds approximately to the midtrimester of human gestation). Thus, hormonal exposure of the rat's brain can be experimentally manipulated during the period of sexual differentiation by perinatal gonadectomies and injections of various hormones as well as their receptor agonists and antagonists. Such research has revealed that different aspects of sexual differentiation of the rat brain are mediated by different pathways of androgen action in the brain. Adding to this complexity, the extent to which sexual differentiation of the brain relies on particular androgens and their metabolites appears to vary across species. Thus, laboratory findings cannot be automatically or easily extrapolated from one laboratory animal species to the next, let alone from animal models to humans. This section first reviews what is known about sexual differentiation of the brain in rats. Subsequent sections highlight particular aspects of the rat model that do not apply to primates, including humans. The reader is advised to always be cautious when reading materials about human sexuality that discuss sexual differentiation of the brain generically without identifying the species from which particular research findings were derived.

Normal development of the male rat brain requires completion of two processes: (1) masculinization—induction of the male phenotype, and (2) defeminization—removal of the female phenotype. Both processes, although distinct, are largely directed by the same steroid hormone, estradiol, which is derived from testosterone by the action of aromatase enzymes in the brain. Subsequently, the brain-derived estradiol interacts with estrogen receptors. Various hypotheses have been advanced to explain why the brains of female fetuses are not masculinized and defeminized by estrogens of maternal origin or those that originate from their own ovaries. A possible explanation is that peripheral estrogens are bound by proteins that hinder their crossing of the blood–brain barrier.

The binding of estrogens to their brain receptors activates a variety of downstream cascades, one of which involves the upregulation of prostaglandin E2. This pathway mediates the masculinization of sexual behavior in rats but does not affect defeminization of sexual or maternal behavior. Thus, the intracerebral administration of prostaglandin E2 to female rat pups produces animals that are behaviorally masculinized but not defeminized. That is, they exhibit male-typical mounting behavior in addition to the full range of female sexual and maternal behaviors. Conversely, administration of indomethacin, which blocks the synthesis of prostaglandin E2, in male pups, produces animals whose behavior is defeminized but not masculinized. Although estradiol simultaneously defeminizes and masculinizes behavior, those actions are mediated by divergent mechanisms downstream of the estrogen receptor.

Problems inevitably arise when one attempts to draw conclusions about human sexual psychology based on extrapolations from rodent behaviors caused by experimental, prenatal, or perinatal endocrine manipulation. For example, a neonatally castrated male rat that shows a female receptive posture called *lordosis,* when mounted by another male, is considered by some to be “homosexual,” as is the perinatally androgenized female rat that mounts other females. The male that mounts another male is sometimes considered to be exhibiting heterosexual behavior, as is the female that displays lordosis when mounted by another female. In this particular laboratory paradigm, sexual orientation is defined in terms of specific behaviors and postures. In contrast, human sexual orientation is defined not by the motor patterns of copulation but by one’s pattern of erotic responsiveness and the gender of one’s preferred sex partner.

Because of the problems in equating rodent behavior with human sexual orientation, researchers have used a variety of strategies to assess partner preference in animals. This is sometimes done by seeing whether a test animal chooses to approach a male or a female stimulus animal placed in opposite arms of a T-maze. Although some unaltered laboratory animals will spontaneously direct most of their sexual behaviors toward their own sex, animal studies of sexual orientation are usually carried out on animals that have been experimentally manipulated. For example, a genetically male rodent may either be castrated as a neonate (depriving his developing brain of androgens), or particular androgen-responsive regions of his brain may be destroyed. However, in order to activate the display of female-typical behaviors and preferences in such male animals, estrogen injections are also required in adulthood. Similarly, androgens must be given again after puberty in order to activate mounting behaviors in female animals that were exposed to androgens prenatally. Because adult homosexual men and women have hormonal profiles that are indistinguishable from those of their heterosexual counterparts, it remains unclear how findings based on such hormonally abnormal animals say anything informative about human sexual orientation. Studies are beginning to examine the neurobiologic underpinnings of sexual behavior in male sheep that, without any experimental manipulation, do not mount females but instead mount only males. The males that receive mounts are often weak or incapacitated and unable to fend off the mounting sheep. These so-called gay sheep have not been described as displaying the feminized patterns of behavior that in most animal models are associated with developmental androgen deficiency in males.

Ethical constraints make it impossible to test the prenatal hormonal hypothesis in humans. That is, one cannot experimentally manipulate the prenatal hormonal exposure of human fetuses to study the effects on subsequent sexual orientation. However, there are alternative strategies. These include assessing sexual orientation in individuals with known or suspected prenatal hormonal abnormalities and assessing presumed correlates of prenatal hormonal exposure in known homosexual and heterosexual individuals.

ORIENTATION FOLLOWING DOCUMENTED PRENATAL HORMONAL ABNORMALITIES: DIFFERENCES/DISORDERS OF SEX DEVELOPMENT/INTERSEX CONDITIONS. The prenatal hormonal hypothesis would predict that an increased proportion of men with medical conditions known to involve prenatal androgen deficiency or insensitivity would be homosexual or transsexual. The same expectation would hold for women exposed prenatally to excess androgens. Because androgens are required for the development of the external male genitalia, intersex individuals may be born with external genitals that are intermediate in morphology between those typical for males and females. Affected individuals, historically referred to as *hermaphrodites* or *pseudohermaphrodites* (depending on their gonadal status), were later referred to as individuals with *intersex conditions* and currently as individuals having *differences or disorders of sex development* (DSDs).

The incidence of homosexuality (relative to the sex assigned at birth) is increased in some intersex conditions, particularly among female-assigned individuals who were exposed to elevated androgens prenatally. Interpretation of these results, however, is complicated by several complex variables. For example, the rearing of individuals born with external genitalia that are not clearly male- or female-typical may not be unambiguous with regard to the assigned gender, despite the intentions of physicians and parental figures. This may occur when the affected individual has had multiple surgeries in an attempt to construct stereotypically normal-appearing genitalia. Even surgeries performed so early that the individual has no memory of them may leave physical scars or other anomalies that give rise to concerns about gender. Moreover, parents may remain ambivalent about the gender of the intersex child and communicate this unwittingly and nonverbally to the child. Thus, studies that detect an increased incidence of lesbian or bisexual identity, behavior, or fantasy in female-assigned individuals with somatic intersex conditions do not provide unequivocal support for the direct model of androgenic effects on sexual orientation.

Individuals with *complete androgen insensitivity syndrome* (CAIS) due to mutations of the androgen receptor are an important exception to the rule of increased homosexuality among female-assigned individuals with intersex conditions who were exposed to elevated prenatal androgens. These individuals were exposed to high androgen levels in utero; however, their tissues lack the capacity to respond to androgens. Therefore, their external genitalia follows the path of female differentiation, although they are genotypically male and have normally functioning testes. Because of their external appearance, they are assigned as females at birth and reared as such. Until relatively recently, they often remained undiagnosed until puberty, when they failed to menstruate. Despite having all of the known metabolic machinery and receptors necessary to act on the brain to both defeminize and masculinize sexual behavior in the rat, the vast majority of adult individuals with CAIS have been described as maintaining a female gender identity and exhibiting stereotypically female behavioral patterns and interests, including sexual interest in males. These observations led some to suggest that in contrast to rodents, male-typical differentiation of the human brain is mediated by the activation of androgen receptors and does not require that androgens be first converted to estrogens.

PRESUMED CORRELATES OF PRENATAL HORMONAL EXPOSURE IN HOMOSEXUAL INDIVIDUALS. Another strategy in attempting to establish a link between prenatal hormonal exposure and sexual orientation has been to examine presumed correlates of such exposure in known homosexual and heterosexual individuals. The most obvious correlates would be abnormalities of testicular or ovarian function and abnormalities in the differentiation of the external genitalia. Such variations are rare in homosexual individuals and lend no support to the prenatal hormonal hypothesis; however, androgens could influence genital development and sexual orientation at different periods of development. Alternatively, differentiation of the substrates that mediate sexual orientation could be orchestrated by an as-yet unidentified androgen-mediated pathway that does not influence the other variables studied. Animal research suggests two additional correlates of early androgen exposure that have been explored in humans as possible correlates of sexual orientation: The pattern of luteinizing hormone secretion by the pituitary gland elicited by estrogen and neuroanatomical sexual dimorphisms.

LUTEINIZING HORMONE RESPONSES. In rats, exposure of the developing hypothalamus to aromatizable androgens (i.e., androgens that can be converted to estrogens) determines the signal that the adult’s brain will relay to the pituitary gland in response to high levels of estrogen in the bloodstream. If rats do not experience high levels of aromatizable androgens at a certain early phase of development (as in normal males), the adult brain will respond to estrogen by directing the pituitary to increase its secretion of luteinizing hormone; a phenomenon referred to as *positive feedback.* However, if the developing rat brain is exposed to high androgen levels during this developmental period, it will not be able to support this positive feedback response. Thus, in rats, the presence or absence of this positive feedback response can be used to infer the pattern of the brain's early androgen exposure. Specifically, the positive feedback response can be elicited in adulthood from normal females and from males that were castrated during the sensitive period of sexual differentiation of the brain, but not from normal males or from females that were experimentally exposed to high androgen levels during that sensitive period of brain development.

These observations generated speculation that in humans, the response of luteinizing hormone to an injection of estrogen would also indicate the sexually differentiated state of the brain and correlate with sexual orientation. Empirical research in this area has produced conflicting results; however, the current consensus opinion is that this feedback response in humans does not correlate with sexual orientation. Moreover, in humans and other primates, convincing research suggests that the brain mechanism regulating luteinizing hormone is the same in both sexes, rather than taking two sexually distinct forms as it does in rodents. If there is no sex difference in the feedback mechanism, it cannot be argued logically that the mechanism should exhibit atypical sexual differentiation in gay men and lesbian women. Since the positive feedback response is required for cyclical ovarian function and fertility in females, menstruation and pregnancy in lesbian women also support this interpretation.

NEUROANATOMICAL SEXUAL DIMORPHISM. Over the past four decades, sex differences have been confirmed in the size of several brain structures in a variety of laboratory animals. These findings have generated speculation concerning the existence of parallel differences in the human brain associated not only with sex but also with sexual orientation.

Most of the structural sex differences identified involve specific cell groups within a broad region of the rodent hypothalamus that participates in regulating a variety of functions, including sexually dimorphic copulatory behaviors. Like the sex differences in copulatory behaviors, several structural sex differences develop in response to sex differences in early androgen exposure: High androgen levels at the appropriate time lead to male-typical anatomy, whereas low levels lead to female-typical anatomy.

Consequently, behavioral sex differences are thought to be mediated, at least in part, by structural differences.

The best-studied anatomical sex difference involves a cell group that straddles the medial preoptic and anterior regions of the hypothalamus—the sexually dimorphic nucleus of the preoptic area (SDN-POA). In the rat, this structure is five to eight times larger in males than in females. Damage to the preoptic region decreases mounting behavior in laboratory animals, whereas electrical stimulation elicits mounting behavior.

The belief that the SDN-POA participates in regulating male sex behavior in rats led to the search for a comparable nucleus in humans. A cell group called *nucleus intermedius* but also known as the *first interstitial nucleus of the anterior hypothalamus* (INAH1), was described by one laboratory as being larger in men than in women and was, therefore, prematurely designated as the *sexually dimorphic nucleus* (SDN) in atlases of the human hypothalamus. Of four laboratories that examined this nucleus for variation with sex and sexual orientation, only one found it to vary with sex, and none found variation with sexual orientation. Its designation as the SDN, therefore, appears to have been premature.

Another structure, the *third interstitial nucleus of the anterior hypothalamus* (INAH3), is perhaps a more promising candidate for homology with the rat's SDN-POA. Three independent laboratories found this nucleus to be much larger in presumed heterosexual men than in women, and one laboratory found the nucleus to contain more neurons in men. By extrapolation from animal work, this sex difference is widely believed to reflect sex differences in early hormone exposure, although, at present, that hypothesis cannot be directly tested in humans. The AIDS epidemic made it possible to study this nucleus from deceased individuals whose medical records indicated homosexual behavior as their HIV risk factor. (Unless someone dies from complications of AIDS, there is usually no documentation of sexual orientation in the medical records available for autopsy studies.) Presumed heterosexual control brains derived, in part, from individuals whose HIV risk factor was intravenous drug use. Those studies found the volume of INAH3 to be smaller in homosexual men than in heterosexual men, but the number of neurons within the nucleus did not vary with sexual orientation. The suggestion of volume reduction must be viewed skeptically for a variety of technical reasons. For example, tissue shrinks in the process of fixation for histologic analysis. This shrinkage influences measures of volume but not measures of cell number. Thus, the finding of equal numbers of neurons in homosexual and heterosexual men may be a more reliable finding than the suggestion of a difference in the volume of the nucleus. Alternatively, the presence of an equal number of cells in a smaller volume could reflect decreased neuropil (e.g., synapses, dendrites) in homosexual men. Decreased neuropil could conceivably reflect low androgens either prenatally or at the time of death due to the antiandrogenic effects of some medications used to combat the opportunistic infections of AIDS patients. A bias could have been introduced into these studies since the majority of heterosexual male subjects with AIDS were intravenous drug users who, compared to gay males, are likely to be less adherent with medication regimens. Additional studies would be required to clarify these issues.

Speculation regarding the function of INAH3 has been based on the assumption that it is the homolog of the rat's SDN-POA. The finding that the size of the SDN-POA correlates positively with the frequency of mounting behavior displayed by male rats established the belief that the SDN-POA participates in regulating male sex behavior. That interpretation, however, is at odds with the fact that the rat's nucleus can be destroyed by electrolytic lesions on both sides of the rat's brain without any discernible effect on mounting behavior. A better case can be made that the SDN-POA functions to inhibit the expression of a female mating posture by male rats. In rats in which intracerebral prostaglandin E2 was manipulated, the volume of the SDN-POA was found to correlate with defeminization and not with the masculinization of copulatory behaviors. Moreover, following lesions that include the SDN-POA, male rats can be induced to display the female copulatory response if they are also injected with estrogen and progesterone.

In addition to the hypothalamus, researchers have sought to identify variation with sex and sexual orientation in the brain commissures, the fiber bundles that connect the left and right hemispheres of the brain. The rationale underlying these studies was drawn from speculation regarding the neuroanatomical basis of statistical sex differences in the lateralization of particular cognitive functions within the brain. Several lines of investigation suggest that women, compared to men, are likely to exhibit more bilaterally symmetrical hemispheric activation while performing particular cognitive tasks. A popular hypothesis holds that this sex difference in brain activity reflects increased interhemispheric communication in women compared to men and that this increased communication between the hemispheres is due to more interconnecting fibers between the hemispheres. More than 50 studies have examined the width or area of particular portions of the corpus callosum, the largest of the brain's commissures, for sex differences. Popular accounts to the contrary, the majority of these studies have found no sexual dimorphism. Studies controlling for variation in the callosum as a function of handedness and aging, however, have found differences in the isthmus of the corpus callosum, which contains axons connecting the right and left parietotemporal cortical regions. These regions mediate functions of language and spatial cognition that are asymmetrically represented and that, according to some studies, vary with both sex and sexual orientation.

NEUROPHYSIOLOGIC MEASURES. A number of neurophysiologic measures have been reported to differ between homosexual men and women and their heterosexual counterparts. Several of these studies report that homosexual individuals exhibit neurophysiologic responses more typical of heterosexuals of the other sex, but to date, none have been adequately replicated by independent laboratories. These include studies of regional patterns of brain activation in response to exposure to putative pheromones. Although positive findings in this area should not be ignored and certainly merit attempts at replication, the existence of a functional vomeronasal organ in humans, thought necessary to respond to pheromones, is itself controversial. In addition, lesbian women have been reported to exhibit masculinized otoacoustic emissions, echo-like waves emitted by the inner ear response to brief sounds, which has been conjectured to reflect increased androgen exposure prenatally. No difference in these emissions has been detected between homosexual and heterosexual men.

ANTHROPOMETRIC CHARACTERISTICS. Several anthropometric characteristics, believed by some to reflect androgen exposure, have been explored in relation to sexual orientation. The characteristics examined include measures of height and weight as well as the amount and distribution of facial hair, the ratio of shoulder width to hip width, the size of the genitalia, and more recently, dermatoglyphic (fingerprint) characteristics, and finger-length ratios. Most of these studies have been flawed in one or more ways, making the occasional positive findings difficult to interpret. Some of these flaws include reliance on self-reports of small, self-selected samples or on measures obtained by raters who were not blind to the sexual orientation of the subjects.

Finger-length ratios have been subjected to considerable investigation for variation with both sex and sexual orientation. The ratio of the length of the second to fourth fingers (2D:4D) was first proposed as a marker for prenatal androgen action in 1998. Since then, over 100 studies have been published testing its association with prenatal androgens or using 2D:4D as a putative marker to investigate the association between prenatal androgens and a variety of outcomes, including sexual orientation. The validity of digit ratios to serve as a marker of prenatal androgen action, however, is highly controversial. Some but not all studies suggest that adult women tend to have longer index fingers (second digits) than adult men relative to the length of the ring finger (fourth digit). In adults, the correlation between the 2D:4D ratio is not high, with a 60% overlap between males and females. The study of congenital adrenal hyperplasia in individuals treated soon after birth has been the gold-standard method for studying the effects of prenatal or perinatal androgens. Examination of the 2D:4D ratio in affected individuals has produced equivocal results. Similarly, study of the 2D:4D ratio as a function of sexual orientation have produced discrepant results. A decreased ratio has been reported with more consistency in lesbian women relative to heterosexual women than has an increased ratio in gay relative to heterosexual men. Nevertheless, the inability to definitively link this ratio to either sexual orientation or prenatal hormone exposure due to inconsistent replication studies does not lend substantial support to the prenatal hormonal hypothesis of sexual orientation in either sex.

PROPOSED MECHANISMS OF ATYPICAL ANDROGEN EXPOSURE. As reviewed above, in men, clinical syndromes involving abnormal androgen function rarely have an impact on sexual orientation, whereas an association between elevated prenatal androgen levels and sexual orientation is statistically demonstrable in women in the context of particular clinical syndromes. Maternal stress during pregnancy and its putative impact on fetal hormone exposure has been examined in relation to homosexuality in men but is no longer widely believed to be a contributory factor.

In multiple samples investigated by one group of researchers, homosexual men have been found to have a greater number of older brothers than heterosexual men. According to these researchers, each older brother increases the “relative risk” of being homosexual by 33% to

48%, and this antecedent older brother effect accounts for the orientation of one of every seven gay men. The hypothesis advanced by these authors is that the late birth order, with more male siblings born earlier, could lead to a progressive immune response of the mother to products associated with a male, which could impair the defeminization and masculinization of subsequent male fetuses. The existence of such “antimale antibodies” is hypothetical, as is the male-associated factor that would trigger their production. Androgens have been hypothesized in this regard; however, under usual circumstances, they are not antigenic. The Y-linked minor histocompatibility locus has also been hypothesized as the triggering factor. Yet, how such mechanisms could selectively impair only certain, less well-established processes, such as the organization of the brain, and not others, like the formation of the genitalia, is not explained by this hypothesis. Nor does this theory explain why the majority of boys late in birth order do not become homosexual, even if their elder brother is homosexual. Finally, the effect has been reported in several studies as applying only to right-handed gay men, while left-handed gay men had fewer older brothers than expected. The biologic premise of the antecedent older brother effect remains questionable, and attempts at replication by independent groups of researchers are needed.

Genetic and epigenetic variations in relation to sexual orientation are areas of current research, as discussed below. Much research in this area considers the hypothesis that genetic or epigenetic mechanisms could affect an individual’s sexual orientation through an impact on hormonal function.

Genetic Research. As in neuroendocrinologic research, some genetic studies have also been premised on the intersex hypothesis of homosexuality. For example, there have been attempts to show that gay men and lesbian women have chromosomal material typical of the other sex in their cells and attempts to link homosexuality with genetically controlled differences in the process of sexual differentiation. To date, these studies have produced negative results. Other genetic approaches, not necessarily wedded to the intersex hypothesis, including heritability as well as genetic linkage and association analyses, have also been employed and have provided some leads.

FAMILY AND TWIN STUDIES. Although homosexuality has been found to run in families, such findings are not helpful in distinguishing between genetic and environmental influences because most related individuals share both environmental and genetic influences. A first step toward disentangling genetic and environmental influences can be made by studying sexual orientation in identical and fraternal twins. One such study assessed sexual orientation not only in identical and fraternal twins but also in the nontwin biologic brothers and the unrelated adopted brothers of homosexual men. The concordance rate for identical twins (52%) in that study was much higher than the rate for fraternal twins (22%). Assuming that environmental influences would be the same for all brothers reared together, the higher concordance rate in the identical twins is consistent with a genetic effect, as identical twins share all of their genes, while fraternal twins, on average, share only half of their genes.

It would be a mistake, however, to attribute the increased concordance rate in identical twins to increased gene sharing alone. If there were no environmental effects on sexual orientation, then the rate of homosexuality among the adopted brothers should have equaled the rate of homosexuality in the general population. Recent studies place the prevalence of homosexuality in men between 2% and 5%. That the concordance rate for homosexuality in adopted brothers was found to be 11% (much higher than in the general population) suggests an environmental contribution. The concordance rate for homosexuality among nontwin biologic brothers was only 9%, a figure statistically indistinguishable from the 11% recorded for adopted brothers. If the concordance rate for homosexuality among nontwin brothers is the same whether or not the brothers are genetically related, then the concordance rate cannot be explained exclusively by genetics.

When considered together, the data from the studies of twins and adopted brothers suggest that the increased concordance for homosexuality in identical twins may be due to a combination of both genetic and environmental influences. Acting via epigenetic mechanisms, environmental influences can induce lasting changes in gene expression without altering the nucleotide sequence of genes. Such environmental influences could theoretically be exerted by the prenatal intrauterine environment as well as by the postnatal environment. Perhaps the most interesting finding to emerge from twin studies is that approximately 50% of identical twins are discordant for sexual orientation even when they are reared together. The discordance in sexual orientation among genetically identical individuals reared in the same family has been consistent across studies and underscores just how little is actually known about the contributions of genes to sexual orientation.

LINKAGE STUDIES. The notion of a *gay gene* has captured the popular imagination. It is worth underscoring, however, that gay genes are not required for homosexuality to run in families or for researchers to determine that homosexuality is heritable. *Heritability* has a precise technical meaning and reflects only the *degree* to which a given trait is *associated* with genetic factors. It says nothing about the specific genetic factors involved or about the mechanisms through which they exert their influence. Furthermore, the concept of heritability provides no information about how a particular trait might change under different environmental conditions. Thus, homosexuality could be highly heritable even if genes influenced sexual orientation entirely through very indirect pathways. The question is often raised as to how genes predisposing to homosexuality could be maintained in the gene pool, assuming that reproduction would be decreased in individuals who carry them. The *Kin Selection Hypothesis* proposes that such genes could be maintained in the population if the costs of not directly reproducing are offset by enhancing the reproductive success of kin, perhaps through altruistic behavior or some other mechanism. For example, one study found increased fecundity among the female maternal relatives of male homosexual individuals and attributed this finding to genes predisposing to homosexuality in men.

Genes alone cannot directly determine any behavior or psychologic phenomenon. Instead, genes direct a particular pattern of ribonucleic acid (RNA) synthesis that, in turn, specifies the production of a particular protein that may then influence behavior. There are necessarily many intervening pathways between a gene and specific behaviors and even more intervening variables between a gene and a pattern that involves both thinking and behaving. The term *homosexual gene* is, therefore, without meaning unless one proposes that a particular gene, perhaps through a hormonal mechanism, directs the brain to develop in such a way that an individual is erotically attracted to others of the same gender. Evidence confirming such a simple and direct link between genes and sexual orientation is lacking.

In 1993, a highly publicized study of markers on the X chromosome presented statistical evidence that genes influencing sexual orientation reside on a portion of that chromosome known as the q28 region. A 1995 study by the same group corroborated the Xq28 linkage in an independent sample of men but found no evidence of an influence of the Xq28 region on sexual orientation in women. In 1999, an independent research team was unable to duplicate the Xq28 finding in men using a comparable experimental design. However, a 2005 genome-wide linkage study (GWLS) that included samples from the 1993 study concluded that genes in the Xq28 region might contribute to sexual orientation in men in some families but found no linkage to Xq28 in the full sample. A more recent GWLS implicated genes in a broader region of the X chromosome that includes the Xq28 region in male homosexuality and additionally implicated genes in a region of chromosome 8. The mechanisms by which genes in these regions might influence sexual orientation in men remain speculative. Such speculation includes the possibility that such genes increase sexual attraction to men in both men and women, leading to increased reproduction in women and, therefore, maintaining the genes in the population. Candidate genes, including the androgen receptor and aromatase enzyme, have also been investigated for variation in sexual orientation with negative results to date. These genes were chosen for examination because of their role in sexual differentiation of the brain in laboratory animals. As noted above, however, evidence for a role of the aromatase enzyme in sexual differentiation of the primate brain is currently lacking.

GENOME-WIDE ASSOCIATION STUDIES. While twin and family studies, including GWLS studies, suggest that sexual orientation is genetically influenced, most genetic studies lack the statistical power to implicate any specific genes in sexual orientation. Genome-wide association studies (GWAS), however, can employ much larger samples than GWLS in order to overcome the power limitation. A 2019 GWAS employed blood samples from 477,522 individuals in the United Kingdom Biobank and 23andMe with replication analyses in 15,142 samples from the United States and Sweden. Samples were coded by sex and sexual history (ever vs. never had a same-sex partner). Five autosomal loci were significantly associated with a history of reporting same-sex behavior and, in aggregate, accounted for 8% to 25% of same-sex behavior with imperfect correlations between sexes. The authors concluded that sexual behavior is influenced by not one but many genes. An important limitation of this study is that it addressed same-sex behavior and not sexual orientation, and there are other traits that might be genetically influenced and affect the odds of ever having had sex with a partner of one’s own sex. For example, openness to experience, one of the “big five” personality dimensions, is genetically influenced and shows a medium effect size difference between heterosexual and bisexual men and women. One might, therefore, hypothesize that openness to experience might have an impact on the lifetime probability of ever having sex with a person of one’s own sex, independent of one’s sexual identity.

Directions for Future Research. Historically, biologic research on sexual orientation has been driven largely by the prenatal hormonal hypothesis and has focused on the potential role of prenatal androgens. Early androgen exposure clearly organizes the mating behavioral repertoires of laboratory animals; however, it is not clear how the regulation of stereotyped reproductive behaviors in animals pertains to sexual orientation in humans. Nevertheless, it does not seem likely that early androgens influence the adult sexual behaviors of all mammals studied except humans. It is clear, however, that the role of aromatization of androgens to estrogens within the developing brain plays a lesser, if any, role in primates compared to rodents. Although early androgen exposure in human birth-assigned females increases the likelihood of some degree of gynephilia in adulthood, there is no compelling evidence for differences in prenatal androgen levels between heterosexual and homosexual men. One possibility that has yet to be explored is that some yet to be identified mechanism downstream of the androgen receptor plays a role in the development of gynephilia but no significant role in other aspects of androgen action such as external genital development. A variation of such a hypothetical mechanism might preclude the development of gynephilia. Females without this hypothetical variation would then be predisposed to gynephilia following relatively mild exposure to elevated androgens prenatally, whereas men with this variation would be predisposed to androphilia despite normal androgen levels prenatally. Currently, relatively little is known regarding the biochemical pathways that are influenced in the primate brain by the binding of androgen to its receptor. Microarray technologies for full transcriptome analysis offer a mechanism for elucidating these pathways in order to identify candidate genes for further study. As noted above, epigenetic variations, which can be environmentally influenced, could lead to such variations in the effects of androgens in the absence of genetic differences (i.e., differences in DNA sequences). Recent technologic innovations now allow high throughput examination of epigenetic modifications, which are heritable modifications to chromosomes that do not alter the genetic sequence. Large-scale heritability and linkage studies may also provide insights; however, the identification of genes associated with sexual orientation alone will be relatively uninformative in the absence of studies to identify their mechanisms of action. Such mechanisms could prove to be very indirect. The interpretation of such studies should not conflate sexual orientation with sexual behavior since, as noted above, genetically influenced personality dimensions could influence the likelihood of ever having engaged in sex with someone of the same sex, which is very different from experiencing predominant or exclusive sexual attractions to individuals of one's own sex. While GWAS have tremendous statistical power, they will not be informative with respect to the genetics of sexual orientation unless the samples upon which they are based are derived from individuals in which sexual orientation has been assessed, *per se,* instead of, or in addition to an assessment of a proxy variable such as ever having engaged in sex with a member of one's own sex as was assessed in the recent GWAS discussed above.

Cross-Cultural Studies

Ford and Beach's 1951 review of animal and cross-cultural studies, *Patterns of Sexual Behavior,* was ground-breaking in concluding that homosexual behavior (defined as "behavior involving stimulation and excitation of the sexual organs" was widespread within the animal kingdom and apparently universal in all human cultures. More specifically, they reviewed the status of homosexuality in 78 cultures of the mid-20th century and concluded that 48 approved some expressions of homosexual behavior but that 28, including the United States, did not. In disapproving cultures, homosexuality was stigmatized from childhood on into adulthood by ridicule and punishment, and sometimes even the death penalty.

Building on the work of Margaret Mead, Ruth Benedict, and other anthropologists, researchers classified structural types of sexual development and forms of homosexual organization in different cultures. Gilbert Herdt, in particular, explicated cross-cultural models based on his study of ritualized homosexuality among the Sambia tribe of New Guinea and his review of findings from other anthropologic studies of sexual practices. Although traditional developmental theory posits a presumed continuity in sexual development across the lifespan, Herdt instead suggested the idea of "discontinuity" in sexual development to explain variation in the psychologic experience and symbolic meaning of sexuality. He also explored the cultural aspects of fluidity in the experience and expression of sexuality that have defined much of the theoretical discourse on bisexuality.

Herdt also described a typology of homosexuality based on a cross-cultural organization of same-sex sexual behavior. The first type is *age-structured homosexuality,* usually involving older and younger males and generally including a sequential pattern of childhood same-sex practices that yield primarily heterosexual behaviors in adults. An example would be the male homosexual practices of classical Greece (*pederasty*). Manifestations more akin to current conceptualizations of transgender phenomena have previously been referred to as *gender-reversed homosexuality,* which refers to a reversal in the normative binary sex-role dress and behavior for a given culture. Examples of such “gender-reversed homosexuality” were considered to be the Native American *berdache* and the *fa’afafine* of modern Samoa, culturally accepted roles in which anatomically male individuals, assumed many aspects of the female gender role. Today, such phenomena are more commonly considered within the spectrum of gender identity rather than sexual orientation. The third type identified by Herdt is *role-specialized homosexuality,* in which same-sex sexual activity is restricted to certain social roles and positions. This type occurs among the shamans of some Native American tribes who, in following dreams or visions revealing their special status, crossdress and engage in homosexual behavior. Role-specialized homosexuality was also found among certain working-class women in 19th-century China. Finally, Herdt described the *modern gay movement,* consisting of egalitarian same-sex practices, as the fourth type of homosexual organization. Although acknowledging that hierarchical relationships still exist in parallel with traditional forms of heterosexual relationships, he concluded that homosexuality in the contemporary United States (and in other Western countries) is historically unique in that it comprises a sexual orientation, a social identity, and a political movement.

Psychosocial Studies of Development

Classical theories of psychological development posit the origins of adult personality and identity in childhood experience. These theories often lay out presumed linear pathways of development that progress sequentially from childhood to adulthood. In the later part of the 20th century, however, focus shifted to the distinct processes of development during adulthood itself. The development of sexual orientation might be better understood by examining psychological and interpersonal events throughout the lifespan that may be characterized by both continuous and discontinuous patterns of development. There is little empirical research to support the traditional view that early childhood behaviors, sexual awareness, and feelings are definitive precursors of adult behaviors, awareness, and feelings. Further, most psychosocial studies are severely limited by problems of sampling and have until very recently tended to focus on white, urban, openly identified, and community-affiliated gay men and lesbian women. It is not known whether one can generalize the development and experience of the latter group to the experience of individuals coming from other ethnic, racial, or culturally diverse groups. While much current research addresses intersectionality (the cumulative and interactive impacts of multiple social categories) on health disparities and how they affect sexual and gender minority populations, little research has addressed intersectional influences on the emergence of sexual orientation and identity developmentally.

Findings from psychosocial studies vary depending on the research methodology. For example, in the mid-20th century's retrospective studies of adult homosexual patients in psychoanalysis, the narratives these individuals told of their upbringing were often consistent with cultural notions of homosexuality. In other words, how these individuals remembered their early childhood may have resulted from social learning of popular theories of homosexuality, either before or during their psychoanalytic treatment, with subsequent internalization of the theory as part of their life scripts. In addition, many studies of purported childhood precursors of adult homosexuality often take a narrow focus on selected characteristics (i.e., gender role atypicality in boys) associated with stereotyped notions of adult homosexuality. Consequently, such studies tended to ignore the enormous individual variability in patterns of development toward and characteristics associated with adult sexual identity.

Historically, children with marked atypical gender behavior (who might meet criteria for today's diagnosis of gender dysphoria of childhood, or GDC), adults disturbed by their homosexual attractions and/or behaviors and voluntarily seeking psychiatric treatment, and incarcerated individuals served as the primary source of statistics about and models for the psychological development of sexual orientation and same-sex behavior. Actual empirical studies of prepubescent homoeroticism in American society are nonexistent, although there are increasing studies of gay, lesbian, and bisexual adolescents. The potential psychosocial understanding that might derive from ethnographic and other social science approaches to studying sexuality in children has been applied only in other cultures and has thus not been utilized as a tool for the study of the development of sexual orientation or sexual identity in American society. Nevertheless, some theoretical models hypothesize how adult gay, lesbian, and bisexual identities develop in Western society that are based on empirical studies of the specific behaviors and experiences associated with establishing these identities.

Antecedents of Homosexuality in Childhood and Adolescence. Early attempts to describe childhood psychosocial antecedents of adult homosexuality consisted primarily of psychoanalytic formulations derived from the histories of psychiatric patients. These usually depicted trauma, loss, and disturbed family relationships in childhood as causal mechanisms. In contrast, modern sexologists conduct field studies of larger samples of nonpatient populations. These studies are often guided by essentialist views that assume a particular personality characteristic or specific behavior is a reliable predictor of adult sexual orientation. To date, no single set of characteristics or unitary pathway leading to adult homosexuality (or heterosexuality) has been identified.

One robust finding in studies of childhood factors associated with adult homosexuality is the recollection of early gender nonconformity. That is to say, femininity in boys and masculinity in girls appear to be correlated with the development of adult homosexuality, but their predictive power is limited, and any specific relationships between childhood gender nonconformity and homosexuality remain unknown.

More recently, studies have focused on the adjustment, health, and mental health issues of young people who self-identify as gay, lesbian, or bisexual who either present to community centers providing services or who are in college. Over time, adolescents appear to be coming out at a younger age which may cause problems within the home due to a lack of parental acceptance. The U.S. Department of Health and Human Services now requires that all organizations serving runaway and homeless youth be equipped to serve sexual and gender minority/LGBTQ youth, who represent a disproportionate segment of this population.

Acquisition of Gay and Lesbian Identities. Mental health professionals should have some understanding of the theoretical description of gay, lesbian, and bisexual identity development in individuals, as well as the meanings of personal identities at a cultural level. From a social constructivist perspective, the appearance of LGB identities—and the detailed description of their emergence and multifaceted expression within both society and the individual—can be seen as an outcome of both the personal growth and development of the individual and of the cultural evolution of the concept of a "homosexual person."

Models of LGB identity acquisition describe an intrapsychic and interpersonal process whereby a subjective experience of oneself as LGB becomes increasingly congruent with societal perceptions of that identity. This process has been conceptualized as occurring over time, in sequential stages, and in a manner that leads to increasing integration of one's experience of being LGB into other aspects of one's sense of self. Vivian Cass conceptualized the first stage as a period of homosexual self-awareness and possible confusion about the presence and meaning of same-sex erotic attractions. In people who come to identify as gay, lesbian, or bisexual, the period of homosexual self-awareness is followed by a time during which the individual considers accepting these feelings and begins to incorporate them into experiences. In many cases, this phase is followed by an extended phase of growing acceptance of and perhaps even pride in the new identity.

The process of identity development leads to different outcomes for different individuals; it is influenced by interpersonal effects and consequences as well as feedback from others and may be interrupted or terminated at any point. Most models of gay, lesbian, and bisexual identity development incorporate the completion of several events or tasks: *Coming out* or becoming aware of same-sex attraction and disclosing it to others, forming relationships with other gay and lesbian persons, engaging in same-sex sexual behaviors; becoming involved in gay and lesbian activities and communities; establishing significant romantic relationships with persons of the same-sex, and learning how to integrate one's sexual orientation identity into other aspects of the self.

Models of gay and lesbian identity acquisition sometimes present an image of progressive elaboration and synthesis of homosexual orientation with other aspects of the self. However, individuals vary considerably in the degree to which they follow such models. In some persons, the development of a gay, lesbian, or bisexual identity may be inhibited in response to any variety of factors. These include a punitive or harsh internal or environmental response to openly expressing aspects of such an identity or a redirection of one's focus to other developmental tasks, such as schooling or career development. Individuals from certain religious communities may eschew adopting a gay or lesbian identity. As models of gay, lesbian, or bisexual identities historically developed based on experiences of urban White people, individuals who live in other types of communities (e.g., rural areas and communities of color) may participate in same-sex sexual activities yet eschew an identity based on these behaviors.

Individual variations in the extent of development of gay, lesbian, and bisexual identities may result both from prohibitive factors (including stigmatization of homosexuality or gender atypicality), either internal or external, that interfere with optimal personal growth and from normative psychosocial influences, reflecting diverse individual experiences and different adaptational needs. The tasks for any clinician working with these individuals are to appreciate the individuality of identity development in each patient, to understand their particular psychological and social resources and needs in this area, and to appreciate the risks and benefits associated with life's choices. Each individual will develop their own identity; the clinician can only help to optimize the understanding of the meaning of various options and to establish opportunities for maximizing freedom in making choices and better understanding the ranges of their potential significance.

Homosexuality and Nongay Identities. The complexities involved in establishing a gay, lesbian, bisexual, or other sexual identity require the clinician's tolerance, respect, patience, and sophistication about sexual matters. The different subjectivities one may encounter in working with LGB and other sexual minority patients can often be understood and appreciated in concepts like hiding/revealing, awareness/unawareness, and acceptance/nonacceptance. Patients with same-sex attractions can be helped to understand that their own sexuality will, in part, be shaped by the meanings attributed to homosexuality in a predominantly heterosexual world. The subjectivity of sexual identity is shaped by culture and language, often with little or no regard to prevailing scientific categories of sexuality. Some broad subjectivities, based on the work of Jack Drescher, are identified here to provide clinicians with a way to understand the range of ways in which patients may manage their same-sex feelings (Fig. 21.2–1).

NONGAY ("EX-GAY")

FIGURE 21.2–1. Sexual identities (homosexual orientation constant).

Closeted individuals are unable to acknowledge to others, and sometimes, even to themselves that they have homoerotic feelings and fantasies. From a behavioral perspective, the popular terms *closeted* or *in the closet* may refer to a person who is actively engaging in homosexual acts but concealing them from others. However, from the retrospective accounts of many gay men and lesbian women, the experience of being in the closet is often more psychologically complex. The feeling of same-sex attraction is often unacceptable and, as a result, unavailable to direct awareness or integration into the individual's public persona. It may therefore be hidden from the self as well as from others. A closeted individual may not act on same-sex attractions at all or may do so only in a *dissociated state.* Dissociated feelings are not unconscious, as in the classical concept of latent homosexuality, but they are out of awareness and only sometimes accessible to consciousness at certain times or in certain situations. Subjectively, a closeted man may tell himself he really does not experience same-sex attractions or, if he is aware of the feelings, he hopes they have some other meaning besides homosexuality. This *psychological state of being closeted* is often reported retrospectively by individuals only *after* they have moved on to a later stage. It is also entirely possible for an individual never to leave this stage.

Homosexually self-aware individuals can acknowledge, at least to themselves, that they experience homoerotic feelings. However, these subjectivities and behaviors may vary from individual to individual. A person may choose not to act on the feelings or may act on them in a secretive way. Some behaviorally closeted individuals are homosexually self-aware, and some are not. Some homosexually self-aware individuals consider the possibility of accepting and integrating these feelings into their public persona. For many individuals, as in Cass's model, this subjectivity may be a normative phase in eventually coming out and affirmatively accepting a gay or lesbian identity. Others may not accept these feelings, as in the example of a homosexually self-aware individual seeking a celibate lifestyle as a way of binding and avoiding a gay or lesbian identity that might prove problematic, not only in the context of one's family, social circle, employment, or religion but may be in conflict with other aspects of an individual's identity. For a clinician to assume of a patient that "She is gay but doesn't know it" is to make an external judgment that may offer little insight into the individual's subjective experience. Such a phrase could describe a closeted woman who is truly unaware of her homoerotic feelings; it could just as well describe a homosexually self-aware woman who knows she has these feelings but is trying to prevent others from knowing she has them; and finally, it could describe a lesbian who is out to a limited circle of individuals, recognizes her own sexual feelings, but is selective about revealing them.

A third subjectivity is that of *nongay/non–lesbian-identified homosexual individuals.* These people are aware of same-sex feelings and may act on them but often identify as heterosexual. They may enter into heterosexual marriages, either hoping that marriage will “cure” their homosexuality or prevent others from questioning their sexual identity. “The Down-Low,” for example, refers to a way of living often associated with urban Black men who reject what they perceive to be an identity associated with White gay culture. While aware of and acting on their same-sex attractions, they are often behaviorally closeted outside the community of other men with whom they have sex and may enter into heterosexual marriages. Some men on the down-low who associate HIV risk with “homosexuality” may engage in high-risk behavior but not see the need for either pre-exposure prophylaxis (PrEP) or HIV testing. Because almost all gay men and lesbian women who come out have gone through a phase of rejecting their own homosexual feelings before accepting their own gay or lesbian identity, it is sometimes assumed that all sexual minority individuals will overcome this period of rejection. However, this is not always the case, and some individuals may never accept either their homosexual feelings or identify as gay, lesbian, or bisexual. These people may seek out ways to change their sexual orientation (see below). In an effort to disidentify with homoerotic feelings and activities, some refer to themselves as either “ex-homosexual” or “ex-gay.”

When conceptualizing sexual identities, they should not be thought of as existing on a developmental continuum or as being associated with more or less psychopathology. It should also be emphasized that this approach to understanding individual subjectivities does not view sexual identities as offering any diagnostic information about an individual. In addition, these subjectivities are not mutually exclusive; there is overlap between them and differing motivations within them. Nor are these sexual subjectivities immutable. Although it may be difficult, if not impossible, to change one’s sexual orientation, it is entirely possible to change attitudes about one’s sexuality or how one labels it. As the subjectivities outlined above are shaped by individual and cultural factors, there may be a wide range of psychosocially constructed attitudes and responses that individuals may develop toward their own homosexuality. Furthermore, the subjectivities outlined above have no exact heterosexual equivalents, as ambivalence about coming out either to oneself or publicly is not intrinsic to forming a heterosexual identity.

LIFE STAGE AND CULTURAL ISSUES

The day-to-day lives of lesbian women and gay men may often be similar to those of heterosexual cohorts. However, gay people face unique developmental tasks throughout the life cycle. For example, during childhood and adolescence, young people who become aware of significant attractions to someone of the same sex will need to understand what makes them different from the majority of people around them. Some will choose to disclose their homosexuality to others through the process of coming out, some will wait until they are older to do so, and some will never do so. During adulthood, and depending upon where they live and work, these men and women will confront unique challenges as they try to establish close relationships and create families. They may do so even without traditional, formal rituals that celebrate their relationships or laws to protect their families. However, they navigate life stages, gay men and lesbian women and bisexual men and women will need to contend both with the adversity of having a stigmatized sexual identity, as well as the potentially life-affirming factors associated with finding one's true self, finding one's true partner, and being part of a community where one can be oneself.

Antihomosexual Attitudes

The terms *antihomosexual attitudes* or *antigay and antilesbian attitudes* are used here to refer to a wide range of critical and disapproving beliefs and feelings about homosexuality, gay men, and lesbian women. Antihomosexual attitudes were once considered normative in most social and institutional settings, including in schools, among the police, in the armed services, and within religious organizations. However, as cultural attitudes have shifted, many traditionally antihomosexual groups and organizations have changed their positions. As a consequence of increasing cultural debates about homosexuality, many high schools and universities now offer clubs—gay–straight alliances—for students of all sexual identities to socialize. Many Western countries allow openly gay and lesbian personnel to serve in their armed forces and police departments. Some religious denominations appoint openly gay and lesbian priests, ministers, and rabbis to serve their congregations. Despite these changes, antihomosexual attitudes are still widespread, and it is helpful to identify their potential impact on gay, lesbian, and bisexual patients.

The term *homophobia* refers to fear or hatred of homosexuality and of gay and lesbian persons (*external homophobia*) or the self-hatred that gay people feel for themselves (*internal homophobia*). All LGB persons, to some extent, contend with *internalized homophobia*—they incorporate disapproving societal views of homosexuality and experience these feelings and beliefs as critical self-evaluation.

The effects of internalized homophobia on the development of one's sexual identity will differ widely at an individual level. Among other things, however, these feelings can lead to the suppression or closeting of awareness of one's own same-sex attraction, impair the acceptance of one's homosexuality, and interfere with the integration of one's homosexual orientation into other aspects of identity. For many gay men and lesbian women, internalized homophobia is experienced as a feeling of devaluation and limitation, not only of their homosexuality but of themselves; for some, it may play a role in the development of psychiatric and behavioral symptoms, including depression, anxiety, denial, and perhaps even suicide.

As the term homophobia gained widespread popular currency, it has been generally, if inexactly, applied to a range of other antihomosexual attitudes. The term has been criticized for suggesting that the existence of antihomosexual attitudes in an individual indicates the presence of a phobia or a formal psychiatric diagnosis. However, cultural attitudes are outside the realm of psychiatric classification. Thus, holding antihomosexual attitudes does not necessarily represent the existence of a mental disorder. Research on homophobic attitudes demonstrated that they are correlated with certain demographic and personality characteristics, including sex, geographical location, religious beliefs, lower education, and a high degree of authoritarianism.

Heterosexism is defined as an ideologic system that denies, denigrates, and stigmatizes any nonheterosexual form of behavior, identity, relationship, or community. This system regards heterosexuality as *normal* and *natural* and treats gay and lesbian people as outsiders who are neither. Heterosexism organizes experience from the point of view that naturalizes and idealizes heterosexuality and either dismisses or ignores a gay, lesbian, or bisexual subjectivity. Heterosexist beliefs can serve to enforce "compulsory heterosexuality" in society. Some common expressions of heterosexism include valuing heterosexual relationships over homosexual ones, an intensely felt opposition to gay and lesbian parenting—regardless of individuals' actual parenting qualities—and the belief that lesbian women and gay men are unsuited for certain professions. Heterosexist attitudes are pervasive in Western cultures where most books, plays, movies, and print and television advertising contain naturalized depictions of heterosexuality. Heterosexism is not necessarily motivated by fear or hatred; in many ways, it is primarily self-referential. However, in the experience of many LGB people, heterosexism is frequently experienced as antihomosexual, which is why it is sometimes confused with homophobia.

Heterosexism does not necessarily imply malice or ill will toward lesbian women and gay men. Nevertheless, in extremis, it may equate the nonheterosexual with the immoral and unnatural and serve to rationalize the condemnation of same-sex relationships and behaviors. *Moral condemnations of homosexuality* treat homosexual acts as intrinsically harmful to the individual, to the individual's spirit, and to the social fabric. Those who condemn same-sex activities believe that heterosexist traditions of philosophical, legal, and religious opposition to homosexuality are, in and of themselves, sufficient reasons to forbid its open expression in the modern world. This reasoning led a U.S. Supreme Court majority to uphold the State of Georgia's right to ban same-sex acts in the 1986 case of *Bowers v. Hardwick.* The justices stated that their decision did "not require a judgment on whether laws against sodomy are wise or desirable" but was based on the "ancient roots" of proscriptions against consensual homosexual activity and a longstanding condemnation of those practices in "Judeo–Christian" moral and ethical standards. In other words, their decision justified the censure of homosexuality in the present because it was censured in the past and argued that antihomosexual laws are permissible because they have always existed. Ironically, more than a decade later, that same statute was overturned by the Georgia Supreme Court in the case of a heterosexual male defendant accused of engaging in so-called unnatural sexual practices with a woman. Then, in 2003, the U.S. Supreme Court made a 6 to 3 historic ruling in *Lawrence and Garner v. Texas* when it found the rest of the country's sodomy laws unconstitutional.

Many contemporary, antihomosexual religious authorities speak of embracing the homosexual person, but not the person's homosexuality.

This antihomosexual attitude is sometimes referred to as “loving the sinner and hating the sin.” It derives from a belief that one *chooses* to be “a homosexual” despite prohibitions against it. As they believe all sinners can be saved, antihomosexual religionists believe they have a religious duty to care about those who make immoral choices. It should be underscored that *choice* is a charged word in moral debates about homosexuality. Similarly, at the other end of this cultural divide, gay people believe they *choose* to act on their homoerotic feelings in order to avoid the choice of suffering from the lack of emotional and sexual fulfillment.

Antihomosexual attitudes—in the form of homophobia, heterosexism, and moral condemnations of homosexuality—shape important aspects of development and day-to-day experience in the lives of lesbian women and gay men. Further, antihomosexual attitudes may lead to *antigay or antilesbian violence.* Even in the absence of overt violence, however, antihomosexual attitudes impinge on the completion of normative developmental tasks in some gay men and lesbian women and may delay or prevent successful adaptation and achievement of an integrated sense of self. If a gay person has been assaulted, the experience may be internalized. Even if they have not been physically assaulted themselves, gay men and lesbian women are sensitized to the ways in which members of the dominant culture, either in positions of authority or on its margins, feel they can make threats and do as they please. In addition, many individuals have had verbal assaults directed against them for being gay or lesbian. There is a growing literature of population studies showing that stigmatization of homosexuality can increase mental health problems in communities.

Coming Out and Meanings of Disclosure

Coming out as a gay, lesbian, bisexual, or other sexual minority person has two components: *coming* out to oneself, which entails recognizing and identifying oneself as a sexual minority person, and *coming out to others.* Coming out to oneself is the subjective experience of inner recognition that homosexual desires, which one may have previously viewed as unacceptable, are part of one’s self. Coming out to others entails disclosing one’s same-sex attractions or sexual minority identity to others and is an ongoing process because people are generally assumed to be heterosexual unless they declare themselves to be otherwise. Thus, one may selectively choose to whom they will come out, and under what circumstances, throughout life: when meeting new people at school, at work, or in day-to-day activities. Initially, one may come out to a select few in the hope of finding social reinforcement and support. Some sexual minority men and women may only come out in certain spheres of their lives, for example, within friendship groups, but remain closeted in other areas, such as in the work setting or within families.

Usually, disclosure of one's sexual minority identity involves either *telling* someone else about that identity or *displaying* some commonly accepted signal of that identity. Adoption of certain styles of dress or behavior, residing in neighborhoods where other gay men and lesbian women live, entering into gay and lesbian communities, and involvement in relationships with persons of the same sex may serve to confirm the identity of a sexual minority person. For some, these activities are signifiers of coming out, performed to signal their sexual minority identity to others. However, it should also be noted that many young people with stable, heterosexual identities often play with gender ambiguity. Nontraditional gender performances are not necessarily a sign of homosexuality, and interpreting them as such may lead to confusion about or an inaccurate assessment of a person's actual sexual identity.

Most empirical studies of coming out describe the ages at which gay men have reported events associated with coming out; fewer studies report on the process for lesbian women. However, those studies show, in general, that women tend to have their first sexual experiences and to come out later than men. Younger lesbian women may experience stronger prohibitions against coming out because of intense expectations of heterosexual dating for women. More recent studies have also suggested that coming out as a sexual minority, much like the age of the first sexual experience, is occurring at progressively earlier ages among adolescents and that there is significant variation in the process based on a variety of factors in addition to sex, such as socioeconomic status, education, and ethnicity. The study of various cultures also demonstrates variation in the coming out process based on the degree of sexual restrictiveness of society at large and the individual's family.

A. is a 25-year-old deeply religious man raised in conservative evangelical traditions. He entered treatment complaining of panic attacks and depression, worried that he might have contracted HIV after a recent, first homosexual experience several months earlier. Although his sexual behavior had not been high-risk, A. was certain he had contracted the virus, and repeated negative HIV tests did not assuage his anxiety. However, he gradually responded to a combination of antidepressant medication, anxiolytics, and twice-a-week psychotherapy.

In the first year of treatment, A.'s sexual identity was rarely discussed as treatment mainly focused on his anxieties about HIV, his job, and interpersonal relationships. Gradually, therapy did address the question of his identity. A. declared he had had sexual relations with a college girlfriend and questioned how could he possibly be gay? He also found it difficult to reconcile the idea of being gay with his religious beliefs. For months, he would go back and forth on the question of whether or not he was gay, and if he were, how could he possibly accept that and stay true to his faith. He would cite moral condemnations of homosexual behavior from scripture and modern religious authorities in an effort to dissuade himself (and the therapist) from the possibility of his accepting a gay identity.

A year into treatment, A. casually told the surprised therapist that he had already decided *he was gay* several months earlier. This private, intrapsychic shift in self-identification represented A.'s coming out to himself. He then offered some personal history he had previously omitted, acknowledging not only childhood sexual fantasies about men but that he had fantasized about sex with men while having sex with his college girlfriend.

Following this, a significant part of treatment focused on A.'s anxieties about coming out to his father, whom he described as a religious, conservative man who would *never* accept a gay son. A. had come out to his mother, who told him not to tell his father, with the warning that "it would kill him." Yet each time he had an argument with his father, A. would contemplate writing a "coming out letter." Asked how his father would react to such a letter, A. acknowledged his wish to use it as a weapon to hurt him. When the therapist asked whether A.'s wish to come out reflected his anger and hostility toward his father rather than a wish for openness and dialogue, he decided not to write the letter.

Eventually, A.'s mother told her husband that their son was gay. He then called A. to say nothing anyone told him would make him stop loving his son. This surprised the patient. The therapist pointed out that if his father was not as unaccepting as he had imagined, perhaps he had projected his own lack of acceptance onto his father. This interpretation allowed the patient to locate the feelings of nonacceptance within himself with which he struggled as he tried to reconcile a growing sense of himself as a gay man.

Coming out is a complicated process that involves both internal and external dimensions, occurs across a lifetime, and may vary in different domains of a person's life. Coming out can mean increased comfort with one's own feelings, and this is integral to social and psychological development. Greater ease in expressing one's feelings, both to oneself and to others, can lead to enrichment of work and relationships. However, even persons who "appear" to be gay or lesbian may have never verbally disclosed their sexual orientation, and others who provide no stereotypical indications of being gay or lesbian may have disclosed their identity to most of their family, friends, and coworkers. Some persons who are fully aware of their homosexuality may never disclose this fact to others. Furthermore, the time frame between awareness of same-sex attraction and self-labeling as gay or lesbian may range from less than a year to decades. In other words, each individual's coming out process is unique and multidimensional.

Race and Ethnicity

Intersectionality refers to how intersections of an individual's social characteristics, such as race, ethnicity, social class, gender identity, and sexual orientation, create interdependent systems of discrimination and advantage. It is increasingly considered part of good clinical practice to view each patient through an intersectional lens. That is, one should consider the impact of each of the patient's multiple social characteristics and identities on their experience, including the types of advantage or discrimination directed toward them by the larger society.

Multiple intersectional factors may interact to compound *sexual minority stress,* that is, the stigma and discrimination experienced by sexual and gender minority individuals with multiple marginalized identities. Theirs is the experience of being a *multiple minority.* For example, the cumulative impact of interactions between racism in the gay community and antihomosexual attitudes within segments of the African-American community may outstrip the coping mechanisms of some Black sexual minority individuals. Finding support within either the Black or gay and lesbian communities may be difficult, and integration of potentially conflicting identities based on race, religion, and sexual orientation may be an important need for persons from these groups. Similar issues may arise for persons from other marginalized racial and ethnic groups. Latinx men and women are often influenced by antigay and antilesbian religious attitudes as well as by traditional, heterosexist gender role, and family expectations. Native peoples' concepts of gender, sexuality, and sexual orientation often diverge considerably from European notions of these constructs and may incorporate beliefs about spirituality as well. Asian Americans come from many different cultural groups with diverse attitudes toward homosexuality and gay, lesbian, and bisexual persons. Thus, although membership in a particular group may assist in predicting family, religious, and social reactions to homosexuality; the diversity of backgrounds and intersecting identities within all groups, whether minority or majority, requires careful assessment to better understand each individual's experience.

The expression of sexual attraction and identity may be strongly influenced by religious, racial, and ethnic identities. A range of identities may be experienced as being in conflict with each other, resulting in such strategies as either maintaining complete secrecy about homoerotic feelings, adopting a bisexual rather than a gay or lesbian identity, or even feeling a need to choose between cultural and sexual orientation identities. For some persons, a conflict between identities may lead to profound confusion and alienation from both groups. The integration of potentially oppositional identities may be extremely difficult to achieve, and the difficulty of this struggle must be appreciated and understood by psychiatrists who work among multicultural gay and lesbian populations.

Religion

Individuals from different religious backgrounds may have had exposure to a wide range of attitudes toward homosexuality, and they may or may not maintain ties to the religion of their families of origin. At a social level, religion influences sexual minority men and women who belong to religious groups that present supportive, tolerant, or disapproving views of homosexuality. Religion also has an impact on all gay and lesbian persons, even those who currently identify as atheists and agnostics, because it contributes to shaping cultural and political attitudes toward homosexuality. Many sexual minority individuals attempt to avoid disapproving or condemnatory religious teachings about homosexuality by eschewing any contact with organized religion; others work within their religious community to try to change traditional, unaccepting attitudes about homosexuality; and still, others stay attached to, while perhaps feeling powerless to change, religions that reinforce their own antihomosexual attitudes. Many gay men and lesbian women have actively sought to reconcile their sexual identity and spirituality within traditional religious groups; some have been successful in doing so. Others have moved to create new churches and spiritual settings that affirm their sexual identities and their relationships. For example, the Metropolitan Community Church (www.mccchurch.org) is an international church that does specific outreach to sexual and gender minority people.

Increasingly, religious organizations within American society have been forced to grapple with the meanings of homosexuality, both as a personal issue for their members and their families and as an issue of ongoing theologic contention. A growing number of religious groups have moved toward positions that either tolerate or actively embrace gay men and lesbian women; some are ordaining gay and lesbian priests, ministers, and rabbis. Pope Francis, when asked about his view of gay priests in 2013, responded, “If someone is gay and he searches for the Lord and has good will, who am I to judge?” Other socially conservative religious organizations have vociferously reaffirmed their traditional opposition to open expressions of homosexuality and criticize the morality of individuals who adopt gay, lesbian, and bisexual identities; they are also critical of heterosexual religious authorities who accept those identities. Regardless of one’s personal relationship to religion or one’s involvement with a specific religious group, sexual minority men and women can be affected by religious teachings and beliefs about homosexuality.

Disapproving religious views of homosexuality often become internalized in sexual minority men and women and may have an effect on their psychosexual development, particularly inhibiting the sexual expression and the development of relationships. Religious beliefs that disapprove of homosexuality constitute substantive, ongoing themes in psychotherapy with some gay, lesbian, and bisexual patients. Many of these themes are intertwined with issues regarding family relationships, particularly in sexual minority men and women who have had strict, fundamentalist, or orthodox religious upbringings. Sexual minority men and women who grow up in communities where social and religious activities are deeply intertwined may stop participating in religious activities and become estranged from their families. They may be deeply concerned about the moral implications of being LGB and about their alienation from their coreligionists. Spiritual development itself may be affected by an inability to reconcile the conflicting internal and external messages concerning the erotic and spiritual aspects of the self. Sexual minority individuals who are able to overcome disapproving, religiously based self-evaluations may nevertheless find it difficult to be comfortable with their sexual identity. Even when faced with denigrating judgments of their sexual orientation, some individuals may not be able to, nor do they wish to, disengage from their religions. Many others struggle to establish a connection to a different, more affirming spiritual community. Conflicts between religion and sexuality are an important focus in clinical work with religious, sexual minority individuals. Followers of the Abrahamic religions may benefit from direction to scholarly works examining the historical contexts and meanings of the putatively antihomosexual scriptures.

Interaction of Sexual Orientation with Stage of Development

The 2011 Institute of Medicine report, *The Health of Lesbian, Gay, Bisexual, and Transgender People,* endorses a life-course framework that acknowledges that events at each stage of life influence subsequent stages and recognizes that experiences are shaped by one’s age cohort and historical context. In general, many of the psychosocial issues confronting sexual minority individuals during different developmental stages are the same as those for heterosexual persons. However, issues specific to being gay or lesbian occur during childhood, adolescence, young adulthood, midlife, and old age. While developmental tasks across the life stages do not take place at the same age for all persons, most sexual minority individuals will have to confront certain tasks during each stage of development.

Childhood. Based on retrospective accounts from adults, children who grow up to be LGB often struggle with feelings of being different from an early age. For some of these children, there is an additional and perhaps related issue of atypical gender role behavior. Feeling different can lead to a sense of alienation that may result in social isolation. Boys who are not stereotypically masculine may be shunned, humiliated, derided, and bullied by their peers in school and other social settings, leading to future difficulties with self-esteem. Girls may be less subject to this process, at least until adolescence, as “tomboy behaviors” in girls are usually better tolerated than so-called effeminacy in boys. Nevertheless, children with gender-atypical behavior are often criticized or otherwise devalued within their own families and sometimes even by mental health professionals. Some parents, believing they might prevent their child from growing up to be LGB, may try to shape developmental outcomes toward more typical gender role behaviors in their children. There is no research supporting the theory that homosexuality can be prevented by attempts to force children to behave in a more gender-typical fashion. Other parents may ignore or distance themselves from children who fail to conform to parental expectations of conventional, heterosexual development. These experiences can lead children who grow up to be LGB to internalize rejecting reactions of others as they come to devalue aspects of their selves that they come to view as unacceptable to others and which they ultimately come to associate with atypical sexuality. When this process is accompanied by incidents of either overt discrimination or violence, the child may suffer lasting impairment in the capacity for psychological and social adaptation.

Adolescence. Adolescence is a particularly vulnerable time for most young people. It is during this period that they must establish a coherent identity, separate from their families of origin, and practice patterns of relating and working that will be further developed in early adulthood. Many LGB youth first become aware of their same-sex attraction during puberty when they begin to mature physically. From retrospective accounts, LGB adults often recall a budding cognitive awareness of their same-sex attractions during adolescence. Many youth, who will subsequently identify as LGB, are involved in heterosexual relationships during this time. However, some of them may enter the early stages of establishing an LGB identity, as they begin to have affectional and physical relationships with persons of the same sex. Some adolescents may go on to develop connections with community structures, such as gay–straight alliances, LGB youth groups, and LGBT community centers. These activities can be either inhibited or facilitated by the reactions of families, relatives, teachers, religious leaders, and peers.

A 2009 adolescent study by Ryan et al. found family rejection of their LGB children increased rates of depression, substance abuse, suicidal ideation, and suicide attempts. Fear of parental rejection may explain why many gay and lesbian adolescents, either consciously or unconsciously, delay some aspect of the development of their sexual identity until they are older. Often, they obtain a greater degree of safety and support by going away to school, moving to an urban environment that allows more anonymity and acceptance, or creating a hometown network of friends who will be accepting of a sexual minority identity. Some adolescents may suppress any awareness of their same-sex attractions; others may defensively attempt to establish a heterosexual identity and relationships, while still others may consciously avoid any outward display of an LGB identity. Less often, but with increased frequency in urban settings, LGB youth may openly identify their sexual orientation at an early age, disclose their feelings to others, and complete significant aspects of LGB identity formation during adolescence. Even outside urban settings, this process has also been greatly facilitated by access to the Internet, where LGB youth can more easily find one another. It remains to be seen whether future generations of young people will follow in the footsteps of an older generation whose members often entered into unsatisfactory heterosexual relationships and eschewed intimate relationships with persons of the same sex out of fear of disclosure of being LGB.

Despite the rapid social changes taking place, there is still an ongoing stigma associated with being LGB. Where there are few adult role models and inadequate resources for support, discrimination, and violence are often directed against visible LGB youth in schools. In the absence of recognition and affirmation from parents and other adult figures in their lives, most pregay and prelesbian adolescents undoubtedly continue to experience significant difficulty in nonaffirming environments. Recent studies show that sexual minority adolescents are at increased risk for anxiety, depression, suicidality, and substance abuse and that bullying between the ages of 12 and 15 years of age was associated with the subsequent presence of anxiety disorders.

Young Adulthood. The period of transition from adolescence to adulthood is a time when many sexual minority individuals have their first opportunity to come out and establish sexual minority identities independent of their families of origin. Sexual minority individuals in their 20s and 30s confront the same developmental tasks as heterosexual peers. These include developing a career, establishing a social identity, developing intimate relationships, and, increasingly for some, raising children. However, for LGB individuals, compared to heterosexual cohorts, these tasks may be accomplished in different ways and at different times than for their heterosexual cohorts. Although heterosexual men and women may be seriously dating, getting engaged, and getting married, closeted sexual minority men and women may date and marry members of the other sex as they struggle to avoid the stigma of homosexuality. Such hiding activities may cause a delay in the consolidation of an integrated sexual identity. Others may sublimate their sexual energies entirely and invest greater efforts in careers. The delays and omissions that follow the secrecy surrounding LGB adolescence can have developmental consequences. For example, some gay men and lesbian women in their 20s and 30s may appear, in some respects, to behave from a developmental perspective somewhat like adolescents. In some urban settings, such individuals form cliques, in-groups, and out-groups with a strong emphasis on style, conformity to standards of dress, a hierarchy of popularity based on looks, athleticism, and affability, as well as opportunities for experimentation with sex and drugs. For some individuals, this “delayed gay adolescence” provides opportunities denied to them when they actually were adolescents: To learn peer and social skills they may not have yet acquired and to experiment with public enactments of their sexual identities. The psychiatrist might view these relational patterns as understandable for those who, in adolescence, had to hide their sexual feelings, behaviors, and identities. Psychiatrists may find it helpful to contextualize risky behaviors related to sexuality, alcohol, and other substance abuse within a developmental framework. During early adulthood, many heterosexual persons marry and have children, options that have historically been much less available to sexual minority couples—although that is beginning to change in places where same-sex marriage is available.

In previous generations, a significant proportion of young adult men and women with predominately same-sex attractions adopted a heterosexual identity and entered into heterosexual marriages; many also had children and raised families. On June 26, 2015, in its ruling on the case *Obergefell v. Hodges*, the U.S. Supreme Court struck down all state bans on same-sex marriage, made same-sex marriage legal in all U.S. states, and required all states to recognize marriage licenses issued in other states. With advances in reproductive technologies and access to marriage equality, the number of same-sex couples having children has grown, resulting in what has been called a *gay baby or gayby boom* (see below).

Many sexual minority men and women have chosen careers that tend to ensure greater acceptance of their sexual identity. Although LGB individuals are employed, whether openly or not, in every type of profession, often they may feel more comfortable working in fields where they can feel comfortable being out. Nonetheless, discrimination in hiring and promotion has been a problem for gay men and lesbian women, while a lack of legal protections created considerable employment-related stress for many of them. Prior to 2020, only 21 U.S. states had legislation prohibiting employment discrimination on the basis of sexual orientation, while the majority of states offered no such protections. In a landmark ruling on June 15, 2020 (*Bostock v. Clayton County*), the U.S. Supreme Court ruled that an employer who fires or discriminates against an individual for being gay or transgender violates Title VII of the Civil Rights Act of 1964, which prohibits discrimination of the basis of sex. The Court said, “If the employer fires the male employee for no reason other than the fact he is attracted to men, the employer discriminates against him for traits or actions it tolerates in his female colleague.” This ruling thus prohibits employment discrimination on the basis of sexual orientation throughout the United States.

In the past, some sexual minority couples may have delayed raising children until midlife due to multiple barriers. In some cases, their children may be from a previous heterosexual marriage, or they may be adopted or conceived by a single sexual minority parent or two people in a committed same-sex relationship. Although attitudes appear to be changing, some of these parents do not receive the same support from their extended families as their heterosexual counterparts. They may often rely much more heavily on friendship networks and paid childcare. Recent access to legal same-sex marriage, together with increased reproductive options, may shift reproduction in sexual minority couples toward younger ages (see below for a discussion of Gay and Lesbian Parents and their Children).

Midlife. For sexual minority men and women, the midlife decades of the 40s and 50s are characterized, as they are for heterosexual men and women, by the consolidation of career identity, concerns about generativity, emerging problems with their own health, and aging and caring for aging parents. LGB baby boomers who are currently in late middle age and older represent the first generation to have openly come out in significant numbers.

Sexual minority individuals share the same midlife health concerns as their heterosexual cohorts. Some, however, may avoid healthcare or receive suboptimal health care if they fear disclosing their sexual orientation to health care personnel. Due to the AIDS epidemic, from the 1970s into the mid-1990s, many gay and bisexual men were confronted during midlife with issues of death and dying associated usually with later stages of life. Increasingly, as HIV treatments have become more effective, many gay and bisexual men find themselves living with a chronic illness that creates its own ongoing uncertainties about one’s health status.

The Older Adults. Individuals 60 years or older have a wide range of experiences in relation to aging; some will develop serious illnesses and become incapacitated, while others will live healthy lives for several more decades. In addition, the commercial worship of youth tends to stigmatize older adults. All older persons need to deal with the possibility of incapacitating illness and the approach of death. Older LGB individuals face additional concerns. For example, they may worry about how they will be treated in assisted living facilities and skilled nursing facilities. In addition, they must confront a widespread stereotype that older LGB people are always lonely and unhappy. Studies, however, have shown older gay men and lesbian women to be as well-adjusted as their heterosexual counterparts. In addition, they may sometimes be better able than younger gay people to contend with the critical reactions to their sexual identities as they may be less concerned about the opinions of others, or they may have come to be more accepting of their sexuality.

The best predictors of psychological adjustment in older LGB individuals appear to be a stable sexual identity and integration into an LGB community. A large majority of older gay men and lesbian women report being happy, deny significant concerns about loneliness or fear of death, and describe good integration into social networks.

Specific problems for older LGB individuals include a lack of adequate resources; reluctance to disclose their sexual orientation to health care and other providers; and an almost total invisibility regarding the needs of older LGB persons, whether single or in relationships, within institutions and agencies that provide care for the aged including nursing homes, supportive living facilities, and hospice care. Failing to recognize LGB people is a function of both the denial of sexuality in older people in general and of an unwillingness to recognize relationships that are not legally sanctioned. Nevertheless, there are a growing number of retirement communities that either cater to older adult LGB people or are "gay-friendly." Social service agencies like Services and Advocacy for GLBT Elders (SAGE, formerly Senior Action in a Gay Environment, www.sageusa.org) have also emerged to provide services for older adult LGBT individuals.

Families and Relationships

Traditionally, gay, lesbian, and bisexual persons usually grew up in families that did not acknowledge or affirm their emerging homosexual attractions or provide them with positive, adult sexual-minority role models. This is gradually changing, as evidenced by LGB adolescents coming out who are living at home and the development of organizations like PFLAG (formerly Parents, Families, and Friends of Lesbians and Gays, https://pflag.org). Nevertheless, not everyone who comes out finds acceptance from their family of origin. In some cases, gay people in relationships do not come out to their families at all, particularly if familial nonacceptance poses a threat to the viability of the couple. Alternatively, many LGB individuals create what has been called *families of choice* or friendship networks. These provide interpersonal bonds, acceptance, adult friendships, and resources unobtainable from their families of origin. Many LGB people go on to form new family structures in their ongoing, romantic same-sex relationships, long-term cohabiting relationships, and single or coparent households with children. Emerging professional literature has begun to describe these couples and families.

Families of Choice. Many sexual minority individuals grew up in families that either ignored, disapproved, or openly denigrated their homosexual feelings and emerging identities; some report significant physical and emotional harm in families that condemned their homosexual orientation. The reactions of parents and other family members to a young person coming out, whether deliberate or inadvertent, can significantly influence the self-esteem and self-acceptance of sexual minority youth. It may irreparably shape the young person's expectations of acceptance or rejection by others outside the family. In the past, LGB youth could expect no more than tolerance within their families; few would receive an active acceptance or empathic support for the experiences and concerns that occur in relation to their emerging sexualities. Greater social acceptance of homosexuality appears to be changing some parents' attitudes toward an increasing acceptance of their LGB children, but this is still a distinct minority position.

Consequently, once most LGB young people achieve sufficient separation from their families of origin, they often create networks of friends and acquaintances who provide them with the support and respect they either lacked or were denied within their families. For a single LGB person, *families of choice* are extremely important; they serve the functions of an extended family. They may help a person pass through developmental crises, are present at celebrations and rituals, and provide a source of comfort and intimacy. In a community that until recently has had little recognition of their primary affectional relationships, these friendships may even be more enduring than romantic relationships, and some even take on greater day-to-day importance than a lover or partner in the life of a particular LGB individual. Understanding and accepting the importance of these friendship networks is essential for the clinician working with LGB people.

Couples. For heterosexual couples, family sanction of marriage provides support and stability. Until recently, same-sex couples often did not find support from their families and, in many cases, even found opposition. This phenomenon is currently shifting toward greater acceptance.

At the time of this writing, same-sex marriage is legal in the United States, Canada, 16 European countries, 7 Latin American countries, Australia, New Zealand, South Africa, and Taiwan. An increasing number of countries and municipalities around the world now legally recognize same-sex relationships through civil unions or domestic partnerships. The 2020 U.S. census reported that 0.8% of all U.S. households are same-sex and that of the 980,000 same-sex households, 52% comprised married partners. Among both married and unmarried same-sex households, there were more female than male couples.

Gay and Lesbian Parents and Their Children. Many lesbian women have conceived, and many gay men have fathered children. In the past, this often took place within a heterosexual marriage that ended when a closeted gay or lesbian partner came out. However, the 1990s saw the start of a *gay baby boom* in which single or coupled gay men and lesbian women began raising children they had either adopted or conceived using reproductive technologies that included donor insemination (using known or unknown donors) or surrogacy. Consequently, in recent years there has been greater visibility of families with gay and lesbian parents, and many younger gay men and lesbian women today seriously consider the option of having children. It is estimated that anywhere between one and fourteen million children live in households headed by same-sex couples.

Numerous studies describe the characteristics of gay and lesbian families and the impact on children of having a gay or lesbian parent. This research was initially undertaken in the late 1970s to evaluate societal concerns and judicial beliefs about the presumed harm done to children who had been raised by gay and lesbian parents. For example, it was not uncommon—and in some states, it is still common—to award custody of children to a nongay parent in a divorce if the other parent comes out as gay, lesbian, or bisexual. These custody decisions were not based on the results of empirical studies but on the belief that LGB parents were either by nature unfit or would influence the eventual sexual identity of their own children. However, the vast preponderance of relevant research strongly suggests that having a lesbian or gay parent has no adverse psychological consequences for children. Nor does having a gay or lesbian parent influence the eventual sexual orientation of children when compared with the children of heterosexual parents. What studies do show is that children with two parents do better than children with one parent, regardless of the sexual orientation of the parents.

LGB parents and their children also have to confront the fact of being different from heterosexual families and may experience stigma or antihomosexual bias. Historically, the ability of both same-sex parents to be legally recognized as parents was prohibited in many states. Consequently, the children in families with same-sex parents were often denied parental benefits from the partner with no legal standing, including clear inheritance rights, death benefits, or the right to be covered by a nonbiologic parent’s health insurance. In response to the needs of these children, in 2001, the American Academy of Pediatrics issued a position statement in support of legal adoption by a second same-sex parent. The APA issued a similar position statement in 2002.

Currently, when a legally married couple has a child, they are both automatically presumed to be legal parents. This presumption applies to same-sex parents when children are born to couples who are legally married or where their state recognizes their civil union or domestic partnership at the time of birth. While most states have not addressed this issue directly, every state that has addressed the issue in its highest court has held that the marital presumption and assisted reproductive provisions apply equally to opposite and same-sex couples. There has been considerable debate regarding the psychological and other quality of life outcomes of the children of same-sex parents. A recent review of 79 scholarly articles on the topic concluded, “Taken together, this research forms an overwhelming scholarly consensus, based on over three decades of peer-reviewed research, that having a gay or lesbian parent does not harm children.” Of the 79 studies reviewed, only four reported that offspring of same-sex couples fared worse.

CLINICAL APPROACHES

Although the psychiatric issues of LGB individuals often resemble those of the general population, there are unique aspects to the clinical work with this patient population.

General Considerations

As many sexual minority patients report having encountered disapproval, discrimination, insensitivity to their concerns, and even abusive treatment within clinical settings, it is not uncommon for them to avoid medical care and to be reluctant about disclosing their sexual orientation identities to clinicians. They may be unwilling to enter treatment without some clear demonstration by the clinician of a nonjudgmental and accepting attitude.

Inclusive and Special Clinical Settings. Sexual minority men and women present for treatment in the same inpatient, outpatient, and residential clinical settings as other patients. In recent years, specialized clinical units and services have been developed, both in the United States and other countries, for working with sexual minority persons. These may include community health centers intended to serve the needs of the local LGBT communities, not-for-profit and for-profit clinics, state and municipal government-supported clinics, and specialized services geared to particular problems like HIV infection or substance abuse. Whether services are provided in general or specialized settings, it is always to the patients' benefit when staff members are trained to deliver culturally sensitive care to sexual minority patients. In fact, multiple studies show that lack of cultural sensitivity in taking a medical history together with lack of familiarity with health matters of particular concern to sexual minority patients contribute to their avoidance of care.

The clinical setting and staff with whom the patient comes in contact are often important determinants in creating a climate of inclusiveness for sexual minority patients. Explicit and implicit communications of acceptance in these settings can ensure successful psychiatric treatment. For example, the language and behavior of psychiatrists and other staff should convey that they do not automatically presume that all individuals, couples, or heads of families are heterosexual (*heterosexism* or *heteronormativity*). Questions about relationships should be open-ended and nonjudgmental when inquiring about the gender of a patient's partner. It should not be assumed that all marriages are heterosexual ones or that married patients are sexually exclusive with their spouses. Questions regarding sexuality should distinguish between desire, behavior, and identity, with the recognition that, especially in younger patients, desires, and behaviors may be more easily described than identity. Many sexual minority men and women report a history of negative experiences in the health care system and may, therefore, enter the clinical setting with a sense of fear and trepidation. The presence of gay-friendly publications or even a rainbow flag in a waiting area can help put sexual minority patients at ease. In addition, self-reporting forms for patients to fill out that neutrally inquire about diverse sexual orientations and family arrangements can reassure LGB persons—as well as those uncertain about their sexual orientation—that they will be treated with respect in this clinical setting and that they can talk openly about their concerns. Since 2011, The Joint Commission (TJC) has required that health care organizations have an LGBT nondiscrimination statement for accreditation to receive Medicare reimbursement. TJC encourages LGBT-inclusiveness in its publication, *Advancing Effective Communication, Cultural Competence, and Patient- and Family-Centered Care for the Lesbian, Gay, Bisexual, and Transgender (LGBT) Community: A Field Guide* which also describes how to create an LGBT-inclusive clinical environment.

Another important strategy in clinical work with LGB patients is to routinely include, when appropriate, references to significant friends and members of nontraditional families during evaluation and treatment. When necessary, same-sex partners and children in these families should be involved in the care of LGB patients. For example, it may be important to obtain corroborative information from partners, to identify potential sources of a patient's problems within the context of the couple or family, or to include a partner in maintaining adherence. In addition, issues of confidentiality and decision-making in working with heterosexual families should also apply to working with gay and lesbian families.

In general, physicians should be conversant with advance directives such as the durable health care power of attorney and the appointment of health care proxies within the states in which they are licensed to practice. These issues may be particularly relevant when working with sexual minorities and alternative families. Historically, same-sex couples did not have marriage rights and found other ways to protect their relationships and families of choice. Even today, some committed couples have not availed themselves of the right to marry. In cases where one of the partners becomes incapacitated, courts may grant important medical decision-making rights and privileges to biologic family members and exclude the wishes of long-term partners. Clinicians should address this important issue with their sexual minority patients.

The Sexual Orientation of the Psychiatrist. The issues of the psychiatrist's sexual orientation and of disclosing this orientation to the patient are complex. The heterosexist assumption that everyone is heterosexual usually means that a psychiatrist's sexual orientation does not come up in treating most patients. However, this assumption does not hold when treating sexual minority patients. A heterosexual psychiatrist trained to be nondisclosing may refuse to answer questions about their sexual orientation and turn the question back on the patient. In general, this might be an error for many sexual minority patients. Not disclosing could be interpreted by a patient as meaning that the psychiatrist is not entirely comfortable speaking about themselves or about homosexuality in general, that the psychiatrist might be closeted, or some other meaning.

In the cases of sexual minority patients working with psychiatrists who are openly LGB, there are several possible benefits and risks to self-disclosure. The benefits of working with a psychiatrist of the same-sexual orientation may include an easier rapport; greater efficiency resulting from shared knowledge about experiences associated with being LGB; if the therapist is older, an ability to share knowledge about the gay community with a younger patient; and affirmative role modeling if the therapist has established a secure LGB identity. Possible risks for such therapeutic dyads include unwarranted assumptions that the patient and psychiatrist share experiences or personal characteristics based on sexual orientation identity alone; reducing the focus of treatment to sexual orientation identity issues alone; transferential or counter-transferential overidentification of the therapist or patient with each other; or shared, unconscious collusion to avoid discussing painful events or affects associated with LGB development.

How an LGB psychiatrist's sexual orientation identity is disclosed to a patient may vary. Sometimes the patient has requested to work with an openly LGB therapist and has obtained this knowledge before beginning treatment. In other cases, the patient learns this information after treatment has begun, either as the result of self-disclosure by the psychiatrist or through some outside source. When self-disclosure is involved, the timing of the disclosure may have a significant impact on facilitating or inhibiting the work in therapy. In some cases, it may have no effect at all. It is useful for the LGB psychiatrist to be able to identify those individuals and the clinical situations in which working with an openly LGB therapist might be most helpful.

In general, the psychiatrist's sexual orientation identity should not be the most significant factor in determining clinical outcomes. Any therapist working with LGB patients needs to maintain a conscious awareness of their own antigay attitudes and heterosexist assumptions; possess a reasonable knowledge base about LGB issues; apply gay-sensitive and gay-affirmative approaches to psychotherapy; and obtain adequate supervision, peer supervision, or outside consultation when necessary. Having an openly LGB identity is no substitute for good training, and LGB mental health professionals should constantly strive to improve their knowledge base and clinical skills.

Sexual orientation may be far less significant than other personal characteristics in determining the effectiveness of a psychiatrist in working with sexual minority patients. A gay or lesbian therapist who has not fully come out or established a comfortable identity may have trouble working with patients struggling with similar concerns. Regardless of sexual orientation identity, a therapist who is uncomfortable talking about sexual issues will have more trouble being helpful to LGB patients with such concerns. Ultimately, the degree of empathy experienced and expressed by the therapist for the patient will, in most cases, be an important factor in determining the effectiveness of treatment.

Specific Clinical Issues

There are clinical concerns that are unique to sexual minority individuals, some of which are particular to their sexual orientation identity. The presentation of other concerns that do not directly relate to sexual orientation identity may also be shaped by the fact that a person is gay, lesbian, or bisexual, and as noted above for some persons being a member of a sexual minority group may interfere with, and even prevent, interactions with the health care system.

Societal and Domestic Violence. The problem of *antigay* or *antilesbian violence* is widespread. In 1990, the U.S. government passed a law ordering a study of hate crimes, including attacks on gay men and lesbian women. Because of concerns about antigay violence at the time, the law's passage was the first time the federal government made any affirmative mention of sexual orientation.

One of the most common forms of violence is *gay-bashing:* Gangs of young men descend on neighborhoods or gathering places where gay people meet. Armed with bats, clubs, or other weapons, they attack anyone they believe to be gay. The most sensational case of antigay violence in the United States was the 1998 death of Matthew Shepard, a young man from Wyoming, robbed and killed by two other young men because they perceived him to be gay. The trial of his killers, and the increasing publicity surrounding gay-bashing incidents in general, provoked wider discussion of previously unspoken cultural beliefs. For example, some perpetrators of violence have put forward a *gay panic defense,* arguing that violence is an excusable response by a heterosexual man to an unwanted sexual advance from a gay man. To date, no court has accepted this defense, and in 2014, California became the first U.S. state to ban the use of this defense (as well as the *trans panic defense*) in murder trials. Since that time, 15 other U.S. states have legislated similar bans, and efforts have been made to introduce a similar ban at the federal level.

LGB individuals who have been the objects of violence, or sexual or domestic abuse, may have difficulties in reporting their experiences and seeking help; they often fear disclosing their sexual identities or receiving judgmental responses—and even harassment—from police or social service workers. In other words, antigay violence is presumed to be an under-reported phenomenon because its victims are often reluctant to come forward and face reprisals from the very authorities to whom such incidents are reported. It has also been argued that antigay violence is the inevitable outgrowth of the unexamined beliefs associated with homophobia, heterosexism, and moral condemnations of homosexuality. According to this argument, those who marginalize homosexuality may be either directly or indirectly responsible for the brutality aimed at LGB people. Inevitably, LGB people may have legitimate concerns about potential physical attacks. The problem of violence directed against them is widespread and well-documented and ranges from verbal abuse to homicide. Violence against LGB people may be committed by strangers, family members, gangs, fellow soldiers within the military, and sometimes by authority figures, such as the police.

Although some therapists believe that childhood sexual abuse causes homosexuality, studies show no causal connection between the phenomenon and the adult development of a gay, lesbian, or bisexual identity. Studies show that sexual abuse of sexual minority individuals during childhood appears to occur at about the same rate as in the general population. Studies of domestic violence and abuse in lesbian and gay relationships demonstrate that physical abuse occurs at about the same rate as in heterosexual relationships.

The impact of violence on sexual minority individuals, as on other victims of violence, includes post-traumatic stress disorder, depression, and a range of other psychological and emotional problems. These include feelings of inadequacy, embarrassment, or shame. In addition, there may be specific symptoms associated with being part of a stigmatized minority group. For example, the victims of antigay or antilesbian violence may hold themselves responsible and believe that their homosexuality caused the assault. The experience of violence can lead an individual to deny a gay or lesbian identity or to avoid other LGB individuals. Depending on the circumstances, the treating psychiatrist should be prepared to respond to the immediate crisis following an incident of abuse or violence, to the potential long-term effects of these events on the individual; and to the ongoing concerns of all sexual minority individuals about potential violence being directed against them.

The psychiatrist can be helpful by recognizing the influence of exposure to antigay violence on the personalities and experiences of gay, lesbian, and bisexual persons and carefully identifying the intrapsychic and interpersonal wounds they may produce. It is also reasonable for psychiatrists and other clinicians to acknowledge the everyday dangers that sexual minority individuals face or may have faced. A psychiatrist can be most helpful by being sensitive to patient anxieties regarding antihomosexual attitudes, as LGB patients can be retraumatized when clinicians deny or minimize the extent to which the phenomenon colors their lives and affects their self-esteem. It should be noted that in many cultures, antihomosexual attitudes are ubiquitous, and no one is free of them, not even psychiatrists. This obliges clinicians to understand and be aware of the ways in which these attitudes may have affected the development of their own identities and belief systems. Such awareness can help psychiatrists to come to a greater empathic appreciation of the impact of antihomosexual attitudes on the gay, lesbian, or bisexual patient they are treating.

Suicide. Determining the rate of suicide attempts and completed suicide among LGB persons is difficult. Factors complicating this research include the reluctance of many individuals distressed about their same-sex feelings to discuss them with mental health professionals, inadequate assessment of sexual orientation in most health care settings, and the absence of information identifying sexual orientation on death certificates. As noted in the aforementioned report of the Institute of Medicine, lack of disclosure of homosexuality poses a greater problem for older compared to more recent studies as social acceptance of homosexuality has increased.

In spite of methodologic difficulties, studies consistently suggest that gay, lesbian, or bisexual youth have an increased risk for attempted suicide. With few exceptions, the increased rate of suicidality among LGB youth in comparison with heterosexual youth is consistent across age groups (i.e., middle school, high school, and young adult populations), gender, race/ethnicity, and differing definitions of sexual orientation (i.e., same-sex attraction, self-identification, and behavior). Suicide rates among gay, lesbian, and bisexual youth may vary on the basis of other risk factors, such as mental illness, substance abuse, rejection by family, and perhaps, degree of gender role nonconformity. For all age groups, an increased risk of suicide may accompany struggles with internalized homophobia, problems with coming out, and difficulty in establishing a firm gay, lesbian, or bisexual identity. At least one study also found suicidal ideation and behavior to vary in sexual minority individuals as a function of race and ethnicity. Compared to Whites, Blacks, and Latinos were more likely to report a history of a suicide attempt; however, they did not evidence increased rates of mental illness. Most of the suicide attempts came at an early age and were interpreted as probably coinciding with the coming out period and likely to have been associated with increased social disapprobation within the Black and Latino communities.

Determination of the exact numbers of gay, lesbian, bisexual, or uncertain people who attempt or complete suicide may be less important than understanding the characteristics that contribute to a risk for suicide. For gay or lesbian youth, enforced invisibility and a lack of adequate resources to address their health and mental health needs can prevent adequate assessment of their concerns or interfere with developing specialized programs for prevention and treatment. Unlike other minority youth, gay, lesbian, and bisexual youth usually do not share their minority status with either parent and consequently may not readily turn to their parents for support. In the United States, this problem has been exacerbated by a socially conservative political climate in which efforts to identify the mental health needs of gay, lesbian, and bisexual individuals are sometimes labeled as an “endorsement” of homosexuality. This has hindered public funding and research efforts to study suicide among gay, lesbian, and bisexual young people, as well as efforts to provide them with social support.

In general, any young person in distress should be carefully evaluated for concerns about sexuality and sexual identity. The psychiatrist should take pains to ensure that assessment and treatment do not place young people at further risk of suicide if and when they disclose their sexual orientation to others. For example, premature coming out, sometimes precipitated by a conversation with a mental health professional, can increase the possibility of rejection by peers and family. Moreover, all physicians should be aware that many parents are hostile to sexual minorities and should assess the risk that the family's attitudes may pose to the patient. These risks may include verbal and physical abuse, subjection to damaging sexual orientation conversion efforts (SOCE), rejection of the child, and even homelessness. Appropriate steps must be taken if the parents cannot provide a safe environment for their child. The potential risk of suicide for persons of any age who are struggling with coming out and establishing a gay, lesbian, or bisexual identity should be recognized. Clinical services appropriate for managing suicidal feelings and behaviors and for providing support to suicidal persons should be available as needed.

Alcohol and Substance Abuse. In response to the 2011 call for the inclusion of sexual orientation and gender identity data in federal surveys, there is now data on alcohol use for sexual minority men and women ages 18 and older from the National Survey of Drug Use and Health (2015 to 2017). The survey includes data from 126,463 individuals, including 8,241 (6.5%) participants identifying as sexual minorities. With respect to alcohol, a disparity emerged by age 25 when alcohol use declined in heterosexual participants but increased in sexual minority men and women until age 50. Gay men ages 18 to 23 had the highest prevalence of alcohol use disorder, while bisexual women had the highest disparity ratio relative to the heterosexual women comparison group.

Another study also employed NSDUH to assess past-year cocaine use, crack cocaine use, heroin use, methamphetamine use, OxyContin misuse, and lifetime use of chemsex drugs (*chemsex* refers to the use of sex-enhancing drugs among MSM). Sexual minorities showed higher odds of past-year substance use and lifetime chemsex drug use. Bisexual women had higher odds for the use of all analyzed substances relative to heterosexual women. Otherwise, being older and being a woman were protective factors. Urbanity, being uninsured, and an unmet need for mental health treatment were associated with significantly higher odds of substance use, chemsex drug use, and binge drinking, established between drug use and health indicators with higher odds of drug use for lower health ratings. Sexual minorities experienced significantly higher levels of socioeconomic vulnerability, which was, in turn, associated with increased odds of drug use. Other recent studies have reported that all sexual minority subgroups are more likely to be tobacco smokers than their heterosexual peers.

Some attribute this increased usage to the psychosocial stressors associated with being LGB. In many cities, bars and clubs where one can enter freely and anonymously are often the first and only point of entry for some individuals into the wider gay and lesbian community.

Recreational or “club drugs” are popular among some segments of the gay and lesbian community. Among these are MDMA (3,4-methylenedioxy-*N*-methylamphetamine), colloquially referred to as Ecstasy, which can induce depression and panic attacks in those who use it. Ketamine, also known as K or Special K, is a dissociative anesthetic that induces feelings of unreality and may cause catatonia. Gamma-hydroxybutyrate, known as G or GHB, is a naturally occurring biologic substance whose effects mimic alcohol. In modest doses, it can cause sleep or coma, and some cases have been fatal in overdose. The psychiatrist working with gay men and lesbian women involved in the club scene or circuit parties should be aware of these particular substances, the lifestyle choices associated with their use, and their potential risks, including potential interactions with prescribed medications.

There are numerous specialized programs, both inpatient and outpatient, that simultaneously address substance use problems while respecting the sexual identities of gay, lesbian, and bisexual persons. There are also 12-step and other self-help programs that provide special groups for gay men and lesbian women and that allow for a more comfortable and open discussion of both sexual identity and substance use issues.

The psychiatrist should be prepared to identify a potential overlap between problems with acceptance of one’s sexual orientation identity and substance abuse as well as the association of substance use with many sexual and gender minority venues. Patients with addiction problems, gay, lesbian, bisexual, or otherwise, sometimes show signs of either a poorly integrated or a self-loathing identity. Such persons may exhibit denial, fear, anger, guilt, helplessness, hopelessness, dishonesty, low self-esteem, self-hatred, and social isolation and alienation. Assessment of these traits and an awareness of how addiction and internalized homophobia may reinforce each other are helpful in providing adequate treatment. Furthermore, it may sometimes be difficult to treat substance abuse problems in gay, lesbian, and bisexual patients without addressing concomitant sexual identity problems. As a result, substance abuse programs that are both gay-sensitive and gay-affirming work best for treating substance abuse disorders among gay men and lesbian women. Prevention or reduction of substance abuse among this population must include the development of settings for socializing without alcohol or drugs.

Talking Sex. As psychiatrists and other health care professionals are often uncomfortable talking about sexuality in general, dealing with the specific sexual behaviors and concerns of gay men and lesbian women may be particularly difficult. Problems may result from either a psychiatrist's unfamiliarity with or disapproval of same-sex behaviors or both. Given the inadequate training in human sexuality in most training programs, it may be difficult for the psychiatrist to discuss the sexual concerns of LGB patients in an objective and comprehensive manner, to be aware of special diagnostic issues, and to approach sex therapy with these men and women. These concerns might include difficulties performing anal intercourse in a committed couple or concerns about HIV infection among gay men, and orgasmic difficulties among lesbian women. Some gay men with HIV develop low serum testosterone and may seek treatment for loss of sexual drive. Some gay men may struggle with issues of sexual compulsivity, and bisexual men and women may have difficulty mastering safer sex practices with one or both sexes.

Patterns of same-sex sexuality have been shown to be different from those in heterosexual couples, with female couples having decreased sexual interaction and male couples initially having increased amounts of sexual interaction in comparison with heterosexual couples. Typologies of male couples have sometimes described them in terms of their degree of sexual exclusivity and openness, and some male couples present with problems related to sexual exclusivity. In contrast, female couples present more often with problems related to decreased sexual desire. There also appear to be generational differences in openness of relationships, which may be attributable to the growing accessibility to legal protections for same-sex couples via marriage or civil unions.

The psychiatrist working with the sexual problems of LGB individuals and couples should consider organic, developmental, interpersonal, and social causes. Assessment and treatment can adapt traditional, heterosexually oriented paradigms of sexuality to include consideration of issues related to LGB development and to the dynamics of same-sex relationships. Special attention should be given to cultural factors that may contribute to sexual problems among gay men and lesbian women. These include a lack of readily available and accurate information about same-sex practices as well as the inevitable internalization of judgmental societal attitudes about homosexuality.

Medical Illness. Although often presented with the same medical problems as the general population, the Institute of Medicine found that lesbian women and gay men experience unique health disparities as well as barriers to equitable health care. One such barrier is psychosocial: Gay men and lesbian women often have to deal with judgmental attitudes from health care personnel which may lead some to avoid or delay seeking care. This may not be as great a problem in some urban settings with large LGBT communities where clinicians, either in private practice or public settings, have experience in caring for lesbian and gay patients. However, even in large urban settings, not all LGB patients have access to health care personnel who are sensitive and knowledgeable about their concerns or their increased risk for some diseases.

There are no gynecologic problems that are unique among lesbian women as opposed to among heterosexual women. Lesbian women, however, may be at greater risk for undetected disease as studies show they may undergo fewer pelvic examinations and Papanicolaou (Pap) smears and mammograms. Sexually transmitted diseases are less common among women who are sexually active only with other women, and there are few cases of HIV infection in these women. Safer sex counseling and screenings must be tailored to the individual’s sexual practices as revealed in taking a complete sexual history. The risk for some types of cancer in women may be affected by factors such as a history of sexual intercourse with men, the number of pregnancies, age at first giving birth, and breastfeeding. Women who have not had children and have not breastfed, have not used oral contraceptives, and are older when they first give birth are at increased risk of breast cancer. Historically, lesbian women have had a lower number of pregnancies than heterosexual women. However, an increasing number of lesbian women have children using reproductive technologies, including anonymous or known donor insemination.

In general, when compared to heterosexual men, gay men who engage in unsafe sexual practices have increased rates of sexually transmitted diseases and HIV infection. Since the 1980s, the influence of HIV infection and AIDS on individual lives and the communities of gay men has been enormous and has affected almost every aspect of the personal and public experience of being gay. Public health campaigns to reduce infection among gay male populations appeared to work for some time in reducing the rate of infection. However, as younger gay men enter the community, educational strategies tailored to older gay men may not reach these new arrivals, and public health responses to their needs have not always been effective. For example, some young gay men may believe that only older gay men are infected with HIV and that they are safe from HIV infection if they only have sex with men their own age. There is also the phenomenon among some gay men of engaging in frequent *barebacking* or *unprotected anal intercourse*, and the rare phenomenon of *bugchasing* when an HIV-negative individual knowingly barebacks with a partner known to be positive. Ignoring public health warnings about HIV has been attributed to different causes, depending on the individual, such as lack of information, taking calculated risks about who is and is not infected (*serosorting*) "AIDS fatigue," and an unwillingness to continue using condoms. Public health measures in this area remain an issue of great concern.

HIV infection—either being infected or knowing someone with the virus—is a potential problem in the life of any gay man who enters the health care system. Health issues related to HIV include testing for infection; ensuring early treatment intervention in infected individuals; preventing further HIV infection; responding to reasonable and irrational fears about contracting the disease; dealing with the chronic stress resulting from either multiple losses, illness, or both; and caring for someone else who is infected. For many gay men, an association of HIV infection with one's sexual orientation identity can exacerbate one's own internalized homophobia.

In July 2012, the Food and Drug Administration (FDA) approved a combination of emtricitabine and tenofovir (trade name Truvada) for PrEP against HIV infection for individuals at high risk. The Centers for Disease Control and the WHO have published guidelines for PrEP in at-risk populations. These guidelines include the use of condoms in addition to PrEP as some men in clinical studies seroconverted despite apparent adherence to the drug regimen. The message to always use condoms has not proved effective in ending the AIDS epidemic; however, programs including PrEP have the potential to do so. In 2014, New York's governor issued a plan to end the epidemic in his state by 2020, specifically to reduce the number of annual new infections from 3,000 to 750. Based on the number of new infections in 2019 (1,700), the goal for 2020 was adjusted upward to 825. The plan includes PrEP, universal HIV testing, and a connection to care for people living with HIV since modern treatments have the capacity to lower viral loads to the point that the risk of transmitting the virus is low. Data from the National HIV Surveillance System suggest that treatment as prevention is being grossly underutilized. Surveillance data suggest that less than half of MSM who are living with HIV are receiving PrEP, although 90% are aware of it. The goal of universal HIV testing and connecting those who test positive with treatment is clearly a public health priority. Integrating antiretroviral therapy for HIV-positive partners and PrEP for HIV-negative partners nearly eliminates the risk of HIV transmission in serodiscordant couples. A newer treatment, postexposure prophylaxis (PEP) antiretroviral regimen initiated within 72 hours of known exposure to HIV, can prevent infection and seroconversion.

There are generational differences. Gay men under 30 years may be untouched by HIV, having never known anyone infected. Those gay men who were out in the 1980s and 1990s have been affected by the epidemic. Among other things, the psychiatrist can play an important role in differentiating functional and organic symptoms that occur in HIV-infected patients, for example, diagnosing the clinical depression that may occur as a result of low testosterone levels, which occur in 30% to 50% of symptomatic HIV infections. Psychiatrists may also be called on to treat any psychiatric sequelae of the disease, including depression, anxiety disorders, psychosis, and dementia. Bipolar disorder is also seen in HIV infection. Control of coexisting psychiatric disorders is crucial to the patient’s adherence to their HIV medication regimen.

Recent advances in treating HIV infection have changed its course from an almost universally fatal diagnosis to a chronic medical condition. However, there are some small, inconclusive studies showing aging-related health problems associated with HIV, such as osteoporosis and chronic obstructive pulmonary disease.

Physical illness in gay men and lesbian women may interact with experiences associated with their sexual identity. In particular, avoidance of healthcare due to fear of stigma in healthcare settings is believed to be a major contributor to sexual minority health disparities. Lifestyle factors, family structures, and social networks can influence the extent and type of support available. The stress of being ill may evoke psychological reactions that affect capacities for intimacy, affection, and sexuality.

Psychotherapy

Gay and Lesbian Affirmative Psychotherapies. The 1970s saw the introduction of literature on *gay and lesbian affirmative psychotherapy.* This approach, a response to the historical pathologizing of homosexuality, was described by Alan Malyon as a "theoretical disposition [that] regards homosexuality as a nonpathologic human potential. The goals of gay-affirmative psychotherapy are similar to those of most traditional approaches to psychological treatment and include both conflict resolution and self-actualization." LGB-affirmative psychotherapy recognizes the centrality of sexual attraction, behaviors, and identity in a person's life but also appreciates that sexual orientation is only one aspect of personality and, depending on the patient's needs and goals, may or may not be a central focus of therapeutic work.

Acceptance, acknowledgment, and affirmation of gay, lesbian, and bisexual persons are essential elements in psychotherapeutic work with sexual minority men and women. These therapeutic stances reflect the therapist's regard and empathy for the patient's sexual feelings and for their same-sex relationships. The therapist's attitudes are meant to offer the patient a contrast to the social denial and denigration that the patient may have experienced in the past. The psychiatrist working with LGB patients should maintain a respectful position that will both help to contain the struggles of the patient and at the same time serve to convey a recognition of the ongoing adverse impact of social prejudice against gay and lesbian persons. The clinician's lack of awareness of or inability to explicitly acknowledge the effects of discriminatory interpersonal and social forces working against the expression of same-sex feelings and desires may suggest to the patient that the psychiatrist agrees with such attitudes.

As the sexual, romantic, and affectionate expressions of sexual minority patients have often been either ignored, ridiculed, or rejected, for many gay, lesbian, and bisexual individuals, speaking about them for the first time with a therapist may represent a unique opportunity. Feeling listened to without judgment, having one's feelings acknowledged as real by a person in authority, and having them affirmed as commonly felt and normal are powerful affirmations. The therapist's ability to tolerate, accept, and validate the patient's feelings allows the patient to express their own antihomosexual feelings and doubts, including fears about the critical reactions of others, disapproving feelings about being gay or lesbian, and regret over losses the patient may have sustained after coming out as gay or lesbian.

Contemporary Psychoanalytic Approaches to Gay and Lesbian Patients. Until the late 20th century, psychoanalytic approaches to LGB individuals focused on homosexuality first as a developmental arrest and then as a “neurotic” symptom. Starting in the late 1970s, newer psychoanalytic approaches emerged. Rather than trying to get homosexual patients to conform to heterosexual norms, these newer approaches see the therapist as an agent of the sexual minority patient.

Analytic work with sexual minority patients has drawn attention to aspects of the therapy process sometimes overlooked in doing psychotherapy with nongay patients. As a result, this approach offers insights into some general principles of psychoanalysis, as well as basic psychoanalytic beliefs and practices, including the nature of the psychotherapeutic frame; the values and risks of therapist self-disclosure; the limitations of psychoanalytic data to support theories of etiology; how adherence to theoretical preconceptions will restrict or inhibit a therapist’s clinical listening; experience-near versus experience-distant responsiveness from the therapist; the therapist’s embeddedness in cultural preconceptions and how they have an impact upon treatment; the role of the patient’s and the therapist’s subcultural identities and how they coconstruct narratives in treatment; and the meanings and therapeutic uses of countertransference. Developing one’s own therapeutic stance in treating sexual minority patients depends on specialized training in psychotherapy, continuing education, the therapist’s own personal analysis, and ongoing self-analysis. Furthermore, the therapist’s stance does not just entail what one knows; it also includes what the therapist does not know and requires an ability to allow a dynamic interplay of knowing and not knowing in the patient, in the therapist, and in the transitional space between them.

An analytically oriented therapist aims to create a therapeutic holding environment, which is a space where all of a patient’s feelings and ideas are allowed to emerge. As in sexual minority affirmative psychotherapy, the analyst’s job is to remain open to hearing the patient’s complaints, sexual or otherwise. In the atmosphere of the holding environment, meanings are discovered, created, and deciphered. All patients, not just sexual minorities, can benefit from a therapeutic holding environment based on respectful principles. Respect for the patient is essential. But by itself, however, it is not enough. The subject of homosexuality often evokes uncomfortable feelings and denigrated meanings. When these emerge in treatment, they certainly need to be tolerated and respected by the therapist. In addition, a prerequisite for doing psychotherapy with sexual minority individuals is for therapists themselves to be able to accept their patients' homosexuality as a normal variation of human sexuality and to value and respect same-sex feelings and behaviors as well. The clinician who automatically regards a homosexual or bisexual orientation as a symptom of some other clinical problem is not engaging in respectful behavior toward the patient. It should again be noted that for some LGB individuals, being treated with such respect by a therapist is a novel experience.

In addition to respect, a contemporary psychoanalytic approach to LGB patients focuses on the meanings, rather than the origins, of human sexuality. The therapist who searches for the causes of homosexuality or bisexuality will ultimately mistake its meaning to the patient for something else. Alternatively, this approach shifts its focus to the affective meanings of the language of the patient, as well as those of the therapist, and to their transferential and countertransferential implications. From this perspective, it is important to understand there are consequences to a therapist's taking sides in a sexual minority patient's interpersonal struggles with family and friends. Everyone a patient discusses should be treated respectfully, including those of whom the patient expresses disapproval. This therapeutic stance allows for a wider exploration of a patient's feelings and identifications with those who accept the patient's sexual identity and those who do not. Patients may try to resolve inner conflicts about being gay or lesbian by selective inattention to (dissociating from) their own antihomosexual identifications. This is sometimes seen in sexual minority individuals who preach rigid doctrine to themselves in order to affirm their sexual orientation identity. Unable to tolerate conflictual feelings about their sexuality, these individuals sound as if they are trying to convince themselves that “It is okay to be gay.” However, this strategy only reverses the feelings and identifications of a former state of mind. In the subjectivity of a closeted identity, heterosexuality is idealized, and homosexuality dissociated. After coming out, being gay can become idealized, while disapproving feelings are denied. For example, a patient's internalized religious beliefs may not be limited to condemnations of homosexuality. They also include moral and ethical beliefs that are integral to the adult self. Patients cannot simply rid themselves of self-condemnatory attitudes without severing their attachments to other important identifications. The psychotherapeutic challenge is to integrate patients' adult feelings and understanding of sexuality, ethics, and morality with their internalized childhood beliefs. Therapeutic holding entails being able to contain all those aspects of the patient so that greater integration of all the patient's feelings can take place.

Sexual Orientation Conversion Efforts. In recent years, there has been an increase in public attention paid to organizations and individuals who make the claim that sexual orientation is mutable. However, most of the arguments for the position that "change is possible" are not taking place in scientific journals but on religious websites, in the popular press, and in social media. It appears that the goal of these efforts has not been to convince the mental health professions that homosexuality can be changed but to market to the public the idea that it can.

The audience for this advertising approach is individuals with same-sex feelings or attractions who do not wish a homosexual identification. These individuals, often for religious reasons, although not always, are unable or unwilling to accept their homoerotic feelings as normal, natural, or moral. Toward that end, they may seek support from family members and friends, coreligionists, and professionals who also disapprove of homosexuality. Such individuals may seek clinicians who claim to be able to change sexual orientation through *sexual orientation conversion efforts (SOCE).* These can include approaches that go by the name of "reparative therapy," "sexual reorientation therapy," or "sexual conversion therapy." Referring to homosexuality as "unwanted same-sex" attractions is a more recent marketing tool. Those unhappy about their homosexuality may seek religious fellowship among the so-called "ex-gay groups."

APA issued its most recent position statement on the subject in 2020:

> APA condemns any practice that aims to change one's sexual orientation or gender expression in the form of conversion therapy, or any other similar type of therapy, as ethically and morally wrong and, additionally, these practices represent a significant risk of harm by subjecting individuals to forms of treatment that have not been scientifically validated. (Reproduced with permission from the American Psychiatric Association. *American Psychiatric Association Position Statement on Same-Sex Orientation*. American Psychiatric Association; 2020.)

In taking such a position on SOCE, organized psychiatry has acted to protect patients who may be harmed by those procedures. Anecdotal reports indicate that unsuccessful conversion therapies may cause depression, intimacy avoidance, and sexual dysfunction. In 2009, the American Psychological Association issued a report of its *Task Force on the Appropriate Therapeutic Response to Sexual Orientation.* The Task Force conducted a systematic review of the peer-reviewed journal literature on SOCE and concluded that efforts to change sexual orientation are unlikely to be successful and involve some risk of harm. Starting with California in 2012, more than 20 U.S. states and Washington DC have passed laws banning licensed clinicians from the practice of SOCE with minors, and similar bans have been introduced in the legislatures of other states. In 2016, Malta became the first country to ban SOCE for individuals of all ages, and in 2020, Albania and Germany issued similar bans. Most telling, in 2013, one of the largest ex-gay organizations in the world, Exodus International, closed operations, at the same time apologizing for any harm their message of “cure” may have inflicted upon the gay community. In 2020, a United Nations Independent Expert on Sexual Orientation and Gender Identity appointed by the UN Office of the High Commissioner for Human Rights issued a report calling for a “global ban on conversion therapy.”

Nevertheless, some individuals may still wish to change their sexual orientation for religious or other reasons. Clinical exploration of the irrational aspects of patients’ internalized antihomosexual attitudes does not always lead to acceptance of one’s homosexuality. Thus, even if homosexuality per se is not a mental disorder, psychiatry, and other mental health professions may wish to find a way to help individuals who wish to rid themselves of same-sex feelings. However, this does not and should not require redefining homosexuality as an illness. If psychiatry and other mental health professions are to play a role in assisting such patients, perhaps the field of plastic surgery might serve as a model: Cosmetic plastic surgeons routinely treat nonpathologic but socially stigmatized physical conditions.

Plastic surgeons, however, employ standards of care that are not matched by those of sexual conversion therapists, who have yet to develop anything approaching scientific and clinically sound selection criteria for patients. It also is not certain that contemporary conversion therapists can develop more exacting standards of care. For example, after the mental health mainstream endorsed a normal variant model, social acceptance of homosexuality increased. Concurrently, the professional training, credentials, and standing of sexual conversion therapists, in general, have diminished. For example, one study showed that conversion therapists regularly violated professional codes of conduct regarding informed consent, confidentiality, pretermination counseling, and provision of referrals after treatment failure. A field dominated by medically trained practitioners half a century ago is now primarily the province of less rigorously trained and sparsely regulated clinicians, pastoral counselors, and self-help groups. In addition, as many conversion therapists work primarily within a faith-healing model, it remains to be seen whether they can successfully develop scientific and clinical selection criteria to identify individuals who may be harmed by SOCE. Until this can be accomplished, the dictum to "first, do no harm" should be kept in mind for those concerned about the well-being and the quality of care for all patients, regardless of their eventual sexual orientation.

ETHICAL AND LEGAL ISSUES

Principle I of *The Principles of Medical Ethics: With Annotations Especially Applicable to Psychiatry* states that:

> *A physician shall be dedicated to providing competent medical service with compassion and respect for human dignity.*

The annotation goes on to say,

> *A psychiatrist should not be a party to any type of policy that excludes, segregates, or demeans the dignity of any patient because of ethnic origin, race, sex, creed, age, socioeconomic status, or sexual orientation.*

There are several ethical and legal issues that may come up in doing psychiatric work with sexual minority individuals. Among these are confidentiality of medical records, a potential for abuse in settings that discriminate against gay, lesbian, and bisexual patients, and maintenance of standards of care.

Information about sexual feelings, behaviors, identity, and relationships should be entered into the medical record only when it is relevant to the evaluation and treatment of the patient and must always be treated in a confidential manner. Court decisions have upheld the status of confidentiality between a therapist and a patient to be as important as a lawyer-client privilege. The U.S. Supreme Court's 1996 *Jaffe v. Redmond* decision, in particular, holds that while medical records may be part of a patient's public medical record, process notes of private psychotherapy conversations remain privileged. In any event, maintaining the confidentiality of an individual's sexual orientation may be an ongoing concern in some cases, particularly where patients may face discrimination if the medical records reveal their sexual identity in the workplace, a health care setting, or from insurers.

Although a clinician's knowledge of a patient's sexual identity is essential to delivering quality of care, the recording of this information in an unprotected medical record (as in a public clinic or in a managed care setting) without informing the patient of this fact may become problematic. Nonclinical communications to others (a clinic's clerical staff, managed care case managers, school officials) about a patient's sexual identity or sexual behavior without the informed consent of the patient are always unethical. When treating patients in settings where total confidentiality cannot be ensured, it is usually best if the psychiatrist discusses with the patient what can and cannot be kept confidential before any personal data are entered into the chart. If or when the patient does not wish personal information to be recorded and if the psychiatrist does not believe this information should be withheld, a referral to another clinician is highly recommended.

There are institutional settings, such as prisons or religious schools and universities, where public knowledge of a person's sexual minority orientation could have adverse consequences for a patient. As in the public sector, the psychiatrist in these settings is employed by a third party and not directly by the patient. Nevertheless, the ethical constraints on the psychiatrist are similar to those in the public mental health sector: The confidentiality of the patient, with the exception of potential harm to self or others, takes precedence over other institutional needs.

Appropriate standards of care in treating gay, lesbian, and bisexual patients require that psychiatrists monitor their own antihomosexual biases when providing assessment and treatment. In U.S. culture, antihomosexual attitudes are ubiquitous, and, consequently, no one is free of them, not even gay and lesbian psychiatrists. This obliges the psychiatrist to understand and be aware of the ways in which these attitudes have had an impact on the development of their own identities. This can help a psychiatrist come to a greater empathic appreciation of the impact of such attitudes on a gay, lesbian, or bisexual patient. Psychiatrists and other practitioners who continue to treat homosexuality as if it were a mental illness engage in such practices outside the mental health mainstream. It is possible that they may risk ethical sanctions, particularly if they violate professional codes of conduct regarding informed consent, confidentiality, pretermination counseling, and provision of referrals after treatment failure. To date, there has been at least one case of a psychiatrist sanctioned by the APA for offering a patient unwanted SOCE. Closeted gay and lesbian psychiatrists struggling with their own identity issues may either need to refrain for a period of time from working with patients who have similar issues or seek supervision or treatment themselves. All psychiatrists, regardless of their own sexual identity, have an ethical obligation to be up-to-date and informed within their field and should regularly undertake continuing education about the mental health concerns and needs of gay, lesbian, and bisexual patients.

TRAINING AND RESEARCH NEEDS

Conceptions of sexuality, sexual identity, and sexual orientation have shifted significantly in the second half of the 20th century and continue to evolve and differentiate as awareness of sexual diversity increases. Increasing awareness of sexual diversity necessitates an expanding lexicon to provide descriptors for newly recognized sexual subgroups and identities. It also necessitates taxonomical and nosologic revisions to provide coherent and meaningful systems of classification and nomenclature. A solid grounding in contemporary theories of sexuality will help psychiatry residents gain the skills and confidence necessary to interact sensitively and competently with persons of all sexual orientations. Competence in working with sexual minorities also entails an awareness that changing meanings in the vernacular and professional terminology may lead to miscommunication unless unambiguous descriptions are elicited to ensure that the mental health professional understands the meanings that patients intend to communicate with their self-labels of identities and behaviors. To facilitate unambiguous communication, it is often helpful for clinicians to review with patients the range of meanings attributed to terms associated with sexual orientation in order to arrive at a mutual understanding of how those terms will be used in sessions.

In addition to training in contemporary sexology, medical school, and psychiatric residency education should review the origins and evolution of the concept of sexual orientation within Western medical discourse. The mechanism of change and the thinking that went into homosexuality's removal from the DSM-II deserves special emphasis. It should be emphasized that the first DSM workgroup to exclude homosexuality was also the first to grapple with the issue of what actually constitutes a mental disorder. After careful study, the scientific committee concluded that homosexuality did not meet the emerging criteria for what constituted a mental disorder that would shape the subsequent DSM-III. Teaching residents this history is not only important to learning about the development of scientific thought, but it is also essential to countering the erroneous but common misconception that homosexuality was deleted by a simple vote of APA members. That misconception contributes to the erroneous perception that the decision was primarily politically rather than scientifically motivated.

Although homosexuality is no longer in the DSM as a disorder, it is important that faculty and trainees learn about the real mental health consequences of being a sexual minority individual, many of which reflect individual responses to antihomosexual attitudes and social prejudice, aka *sexual minority stress.* Although accepting attitudes toward gay, lesbian, and bisexual individuals are increasing, antihomosexual bias remains widespread in society at large and persists within health care systems. The 2011 report by the Institute of Medicine, The Health of Lesbian, Gay, Bisexual, and Transgender People, concluded that the stress due to the stigma associated with being a sexual minority person contributes to the physical and mental health disparities of gay, lesbian and bisexual people As addressed in chapter 21.4, the stigma associated with being transgender contributes significantly to the health disparities seen in that community. The mental health disparities include higher rates of depression, anxiety disorders, suicidality, and substance abuse. Following that report, the National Institutes of Health established the Sexual and Gender Minority Research Office, and numerous rigorously conducted studies have further characterized the impacts of SGM minority stress on health and identified points of interventions. In particular, the report concluded that instruction about the lives and mental health needs of gay men, lesbian women, and bisexual persons should not be restricted to classes on sexual minority issues but should be fully integrated into the cultural competence curricula as well as the broader curriculum on sexuality in psychiatry and other health disciplines. Such cultural competence training should foster an appreciation of the diversity within the sexual minority community and familiarity with the common issues and concerns within sexual minority communities. At the same time, cultural competence training should discourage stereotyping individual patients as each one presents with a unique constellation of issues. Recent surveys report that many psychiatry residents neglect to routinely take adequate psychosexual histories and report discomfort in doing so or not knowing the essentials that are required in particular clinical situations. It is the responsibility of residency training programs to ensure that these training needs are met.

Past and present theories on the origins of sexual orientation and their role in patient care also need to be addressed. Understanding the history of pathologizing etiologic theories and the "therapies" based on them gives trainees some insight into the trepidation with which sexual minority individuals may approach mental health professionals. This knowledge also prepares residents to appropriately respond when patients bring concerns about this history into treatment. It is important that residents understand that sexual orientation is rarely subject to change and appreciate the possible harm caused by efforts to alter a person's sexual orientation. Residents should master the fundamentals of therapies that are affirmative and respectful of an individual's sexual orientation and identity. Given the prominence of biologically deterministic theories pertaining to sexual orientation, residents should also know that the decision to declassify homosexuality was not based on reductive presumptions about etiology or resistance to change. Contemporary gay-affirmative therapies entail acceptance of homosexuality, regardless of any presumptions about its etiology, as a normal variation of human sexuality. Their focus is on identifying and addressing a patient's life problems and conflicts, not revealing why the individual is gay or lesbian. Fear that a heterosexual therapist would focus on their sexual orientation rather than their chief complaints motivates many sexual minority individuals to seek sexual minority therapists who are publicly open about their sexual identities.

Instruction about the mental health needs of sexual minorities must include education concerning obstacles to their health care, many of which are being diminished by recent legislation and policy changes. Nevertheless, sexual minorities, due in part to negative past experiences, may avoid healthcare settings. They may also be guarded about discussing their sexual behavior with healthcare providers, fearing that it will lead to discrimination. Moreover, the use of heteronormative language and failure to inquire about sexuality on the part of health care providers may further discourage patients from disclosing their sexual minority status. Yet, such disclosure is a prerequisite to discussing how that status affects their lives as well as their particular sexual concerns. Alternatively, an atmosphere that fosters disclosure can be perceived as more welcoming and is likely to enhance adherence with follow-up appointments and engagement in patient-centered care.

Although all residents will benefit from contact with respected psychiatrists who are openly LGB, sexual minority residents may particularly benefit from access to sexual minority faculty as role models. National organizations like AGLP: The Association of LGBTQ+ Psychiatrists (www.aglp.org) and the Caucus of Gay, Lesbian, and Bisexual Psychiatrists of the APA can serve as such a resource. Medical schools and professional organizations should increase the opportunities available for training about the clinical concerns of sexual minorities and encourage gay and lesbian faculty and other leaders to be visible and active in a wide range of professional activities.

There is still much to be understood about sexual orientation and how the needs of sexual minority individuals vary demographically and across the life cycle. Training should engender curiosity about these unknowns and awareness of areas in need of further research. Preliminary research has described variations in sexual desire, behavior, and identity associated with a range of demographic and personal characteristics such as sex, age, race, class, geographic location, and religion. Until recently, most studies have focused on White, urban, middle-class men. However, over the past decade, an increasing number of studies have begun to examine the impact of intersectional factors, including race, ethnicity, and socioeconomic factors, on sexual minority physical and mental well-being. Because most studies have been cross-sectional, there is a need for longitudinal studies to investigate the development and experience of sexual orientation and sexual identity over time and across the lifespan. Compared to cross-sectional studies, longitudinal studies may be more helpful in elucidating the factors that shape individual expressions of desire and behavior, as well as contributors to sexual minority disparities in physical and emotional health. Of note, in addition to rigorously assessing sexual orientation and gender identity, many federal health surveys are currently collecting data longitudinally.

Current research has moved beyond traditional biologic and psychosocial approaches to incorporate constructivist approaches that interpret the role of fluctuating cultural and other historical forces in shaping individual lives and experiences.

21.3 Paraphilic Disorders

RENEÉ M. SORRENTINO, M.D.

DSM-5 defines *paraphilia* as “any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal physically mature, consenting human partners.” The term *paraphilic disorder,* as defined by the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5) and its text revision (DSM-5-TR), is used to refer to a paraphilia that is currently causing distress or impairment to the individual or a paraphilia whose satisfaction has entailed personal harm, or risk of harm, to others. Paraphilic interests are more common in men, although not well researched in women, and include a wide variety of behaviors typically seen in clinical populations seeking evaluation and treatment for paraphilias. Those who most frequently seek psychiatric treatment for sex offenses are those accused of or involved in child molestation, voyeurism, exhibitionism, fetishism, frottage, and public masturbation. The term *sex offender* is used to refer to an individual who has been legally convicted of a sex offense. The terminology sex offender does not provide any information regarding the offender’s reason for committing the sexual offense, nor does it indicate the presence or absence of a paraphilia. The psychiatric treatment of sex offenders is distinct from other clinical populations. In many jurisdictions in the United States, sex offender legislation has mandated treatment for offenders deemed “sexually dangerous” or “sexually violent” in psychiatric hospitals where they are civilly committed. Such legislation has generated longstanding debates on the diagnosis of paraphilias, the nature of mental illness, and the treatability of sex offenders. The changes to the paraphilia diagnoses in DSM-5 and DSM-5-TR generated debate about how to conceptualize paraphilias and the adverse legal consequences implicit in identifying certain sexual behaviors as pathologic.

DEFINITION

The definition of sexual deviance or sexual perversities depends on the particular society and culture in which the behavior exists. A behavior may be considered deviant by one society and accepted, albeit unusual, by another. The term *paraphilia* is derived from the Greek words “*para*” meaning next to, and “*philia,*” meaning love. The etymologic definition of paraphilia is “next to or alongside love.” The term paraphilia, therefore, refers to a love that is perverted or “alongside the norm.” In addition to the presence of a deviant sexual interest, paraphilias are characterized by difficulty resisting an impulse for the sexual acts.

DSM-5 made a distinction between paraphilias and paraphilic disorders. The term paraphilic disorders refers to a paraphilia that is currently causing distress or impairment to the individual or a paraphilia whose satisfaction has entailed personal harm, or risk of harm, to others. The definition of paraphilias in DSM-5 changed. Previously, paraphilias were defined as intense, recurring sexual fantasies, sexual urges, or behaviors that involve nonhuman objects, children, or nonconsenting adults, suffering or humiliation (to self or to others), lasting for at least 6 months. DSM-5 defined paraphilia as “any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners.”

DSM-5 and DSM-5-TR include eight specific paraphilic disorders: exhibitionistic disorder (sexual arousal from exposure of genitals to a stranger), pedophilic disorder (sexual arousal to prepubescent individual, generally 13 years of age or younger), voyeuristic disorder (observing others’ sexual activities), fetishistic disorder (use of inert objects, such as female undergarments), transvestic disorder (cross-dressing), sexual sadism disorder (inflicting suffering or humiliation), sexual masochism (being humiliated, beaten, bound, or made to suffer), and frotteuristic disorder (touching, rubbing against a nonconsenting person). Paraphilia not otherwise specified (NOS) has been replaced in DSM-5 with specified paraphilic disorder and unspecified paraphilic disorder as the result of a system-wide standardized DSM-5 change to each residual DSM-IV NOS category.

HISTORY

Societies define normal sexual behavior as that behavior that results in healthy, nonharming sexual contact. Those sexual practices that do not result in healthy, nonharming sexual contact are judged as undesirable and in need of change. Those individuals who engage in sexual behaviors outside this definition are subject to criminal action. Historically, society has created sexual prohibitions that, if breached, have serious legal and social consequences. Of all criminal behaviors, those who breach sexual prohibitions are viewed as the most deplorable. Those behaviors that cause obvious harm to others, such as sexual contact with children or bodily punishment to another, are universally defined as abnormal or sexually deviant. However, those sexual practices that do not harm others are not as clearly defined. Some societies have further defined sexual deviance as sexual practices that are maladaptive or deviations from the social norm. This definition would then include those behaviors that are considered evolutionarily maladaptive and uncommon. Richard von Krafft-Ebing, a German psychiatrist, credited with formally introducing the study of sexology as a psychiatric phenomenon, identified paraphilias first in his 1886 *Psychopathia Sexualis* (Sexual Psychopathy). This highly influential psychiatric text laid the groundwork for the development of research and treatment in this area that has taken place over the past century.

The term *paraphilia* was coined by psychologists in the early 1900s to refer to the sexual variations that were just starting to be researched. Because of a lack of understanding, it included transvestism and other nonsexual variations as well. Previously, these were called *perversions.* Paraphiliacs treated by psychologists were seeking help for behavior they could not control. The word retained this meaning and did not change to include those who were sexually curious.

Sigmund Freud held that human sexuality advanced through stages. He theorized that individuals would progress toward “normal” heterosexuality unless prevented. He saw all paraphilias as infantile, that is, not mature sexual behavior. Because the paraphilias that involved diapers fit well into this theory, they were well-documented. Wilhelm Stekel’s *Patterns of Psychosexual Infantilism* came from this perspective. Homosexuality, sadism, zoophilia, and many others were included in his examples.

As research advanced, Freud’s notion of psychosexual infantilism was replaced with different views. These views dealt individually with the major paraphilias, such as fetishism, masochism, and transvestism. The diaper paraphilias were generally classified into one of these major categories as a result of the author’s viewpoints. In 1987, the third revised edition of DSM (DSM-III-R) used *infantilism* to refer to those who had a “desire to be treated as a helpless infant and clothed in diapers” and categorized infantilism under sexual masochism.

COMPARATIVE NOSOLOGY

DSM originally classified sexual deviations with psychopathic personality disturbances. This classification was based on the belief that sexual deviations were unlawful, and thereby, those individuals engaging in sexual deviations were psychopathic. In DSM-II, sexual deviations were classified as personality disorders. DSM-III changed the nomenclature of these behaviors from sexual deviation to paraphilia. Paraphilias were classified as psychosexual disorders, which included gender identity disorders, psychosexual dysfunctions, and egodystonic homosexuality. DSM-IV-TR reclassified transvestism from a disorder of gender identity to a paraphilia called *transvestic fetishism.* DSM-5 redefined paraphilias, made a distinction between paraphilias and paraphilic disorders, and added course specifiers. The paraphilic disorders are presented in DSM-5 and DSM-5-TR according to the following classification scheme: anomalous activity preferences, which include voyeuristic disorder, exhibitionistic disorder, and frotteuristic disorder; algolagnic disorders, which include sexual masochism disorder and sexual sadism disorder; anomalous target preferences, which include pedophilic disorder, fetishistic disorder, and transvestic disorder.

The question of whether paraphilias are mental disorders was directly answered in DSM-5. In DSM-5, paraphilias are not considered mental disorders unless they cause distress or impairment (criterion B) to the individual, or the paraphilia causes personal harm or risk of harm to others. If a paraphilia causes impairment or harm, it is a mental disorder termed "paraphilic disorder." This change in nomenclature represents an attempt by DSM-5 to preserve the distinction between normative and nonnormative sexual behavior without labeling nonnormative sexual behavior a mental disorder.

DSM-5 was the first edition to add course specifiers to paraphilic disorders. Similar to the course specifiers in other DSM diagnoses, the course specifiers indicate a change in symptoms. The course specifiers are included in all of the paraphilic disorders, with the exception of other specified paraphilic disorder, unspecified paraphilic disorder, and pedophilic disorder. The course specifier named "in a controlled environment" was introduced to indicate the absence of paraphilic urges in settings where opportunities to engage in paraphilic behaviors are restricted. An individual "in full remission" has not acted on the urges with a nonconsenting person, and there has been no distress or impairment in social, occupational, or other areas of functioning for at least 5 years in an uncontrolled environment. The question of whether a paraphilic disorder can be in remission independent of the environment is not known.

Previous editions of DSM attempted to address the diagnostic difficulties and assumptions inherent in the diagnostic category of paraphilias. There is a second group of sexual impulse disorders not currently classified as paraphilias because the particular sexual behaviors affected are not considered "deviant" with respect to contemporary cultural norms. These disorders have been designated as paraphilia-related disorders by Kafka based on the following clinical data:

- The boundary for social as well as sexual deviance is largely determined by cultural and historical context. As such, sexual disorders once considered paraphilias (e.g., homosexuality) are now regarded as variants of normal sexuality; so too, sexual behaviors currently considered normal (e.g., masturbation) were once culturally proscribed.
- Paraphilia-related disorders have been diagnosed in male paraphiliacs, and men selected for studies of paraphilia-related disorders are reported to have paraphilias as well.
- Paraphilia-related disorders can produce a pattern of sexual frequency and intensity with concomitant psychosocial impairment that does not readily distinguish them from nonviolent paraphilic disorders.
- Analogous with paraphilias, the presence of a single paraphilia-related disorder increases the likelihood of occurrence of a multiplicity of these behaviors in an affected person.
- Paraphilias and paraphilia-related disorders can both be ameliorated by antiandrogens and serotonergic antidepressants, such as SSRIs. Disorders of sexual impulsivity can be pleomorphic and may include sexual arousal to behaviors that are socially “deviant” as well as “normal.” In fact, inasmuch as paraphilia-related disorders may be common in paraphiliacs and also occur without the companion of the latter, paraphilia-related disorders may be the more prevalent form of sexual impulsivity. In addition, although the estimated sex difference ratio for paraphilia-related disorders is unknown, protracted promiscuity (e.g., “nymphomania”) and compulsive masturbation are not uncommon behaviors described by women.

The paraphilic-related disorders were not incorporated in DSM. However, DSM-5 considered including portions of these disorders by proposing a new disorder, hypersexual disorder. Hypersexual Disorder was defined as nonparaphilic sexual interests with an impulsivity component. Hypersexual disorder was rejected from DSM due to concerns regarding its diagnostic validity.

DSM-5 proposed broadening the pedophilic disorder diagnosis to include attraction to pubescent as well as prepubescent children. The proposed modified diagnosis, pedophebephilic disorder, referred to a distinct group of individuals who are sexually aroused to adolescents. Ultimately pedophebephilic disorder was not incorporated in the DSM-5.

There has been a longstanding disagreement regarding whether rapists meet the criteria for paraphilia. The category of paraphilic coercive disorder was proposed in DSM-5 for individuals with intense, repetitive urges of 6 months' duration to commit rape, who had either acted on these urges or were disturbed by the urges. DSM has never included rape or paraphilic coercive disorder as a diagnosis.

The changes to paraphilic disorders in DSM-5 represent an attempt to answer the central philosophical question of what constitutes disordered sexual behavior. They include a change in nomenclature and the addition of courses. Previous additions to DSM have attempted to make a distinction between normal and abnormal sexual behaviors. DSM-5 made a distinction between paraphilias and paraphilic disorders, indicating that paraphilias are not ipso facto mental disorders. The basic structure of the diagnostic criteria in DSM-5 is unchanged from DSM-IV-TR.

The World Health Organization approved the International Classification of Diseases, 11th version (ICD-11), which includes the replacement of the section of the "Disorders of Sexual Preference" with "Paraphilic Disorders." Similar to the DSM-5, this change represented a move from stigmatizing unconventional or unusual sexual behaviors to defining pathologic or disordered sexual behaviors.

EPIDEMIOLOGY

Gender Ratio

Paraphilic disorders are predominantly thought to be male sexuality disorders because women rarely present in clinical or forensic settings, and research is limited. In nonclinical samples, however, both men and women report a variety of paraphilic interests. In these studies, men report a higher incidence of sexual interests in sadism, exhibitionism, and fetishism, whereas women report a higher interest in masochism. The reason for this gender disparity is unknown, but the role of gender bias in the reporting and evaluation of sexual offenses likely is contributory.

Paraphilic Populations. The frequency of paraphilic behavior is unknown. The majority of epidemiologic data relating to paraphilias derive from clinical populations. It is difficult to obtain the frequency of paraphilic behaviors in the nonclinical population, as individuals are reluctant to report sexual fantasies and behaviors. In one study of the general population, 61.7% of men reported fantasies of initiating a young girl into sexuality; 33.0% described fantasies of raping adult women; 11.7% described masochistic fantasies; 5.3% described fantasies of having sex with an animal; and 3.2% described fantasies of initiating a young boy into sexuality. A study of college students' sexual behavior revealed that 42% reported having participated in voyeurism; 35% in frottage; 8% in making obscene telephone calls; 5% in coercive sexual activity; 3% in sexual contact with girls under age 12; and 2% in exhibitionism. A total of 65% reported having participated in some variant of paraphilic behavior. Another general population study, including men and women, found similar levels of interest in fetishism and masochism.

In a university study of both men and women, 50.6% of men and 41.5% of women identified a paraphilic interest. Interests in voyeurism, exhibitionism, sadism, and frotteurism were higher in men, whereas interests in fetishism and masochism were greater in women.

Paraphilia Disordered Populations. Those individuals who seek evaluation and treatment are a distinct group. It is unlikely that individuals seeking treatment represent the heterogeneous population of individuals with paraphilias. Some paraphilias are more likely to come to the attention of others because they involve another person (such as pedophilia or exhibitionism). However, those paraphilias that do not involve another person, such as the use of fetish objects, are less likely to be treated. Those paraphilias whose behavior is criminal tend to be overrepresented in clinical populations because they frequently lead to mandatory reporting or court-ordered treatment.

Data gathered from more than 90 treatment programs throughout North America regarding 2,129 cases of individuals seeking assessment indicate that 37.1% had been involved in child molestation; 20.2% in voyeurism; 13.8% in exhibitionism; 13.3% in fetishism; 11.2% in frottage; and 10.7% in public masturbation. A study of 561 paraphilic persons who had committed more than 291,000 paraphilic acts against more than 195,000 victims indicated that, of all victims, 37.3% were victims of exhibitionism; 28.6% of frottage; 13.6% of voyeurism; 11.8% of molestation against boys outside the home; 3.5% of public masturbation; 2.3% of molestation of girls outside the home; 1% of obscene telephone calls; 0.9% of bestiality; 0.5% of rape of adult women; 0.2% of molestation of girls in the home; 0.2% of urolagnia; and 0.1% or less of sadism, masochism, fetishism, molestation of boys within the home, obscene mailings, coprophilia, or attraction to odors.

Frequency of Paraphilic Behavior

The presence of a paraphilia does not indicate whether an individual engages in paraphilic behavior or sexual fantasy. Some individuals never act on paraphilic urges. Rather, they engage in sexual gratification from sexual fantasies. Other individuals carry out paraphilic fantasies. In a study of individuals seeking treatment, the median number of paraphilic acts by paraphilic category are as follows: Nonincestuous molestation of a female victim 1.4; nonincestuous molestation of a male victim 10.1; incestuous molestation of a female victim 4.4; incestuous molestation of a male victim 5.2; rape of adult women 0.9; exhibitionism 50.5; voyeurism 16.5; frottage 29.5; transvestism 25.0; fetishism 3.3; sadism 3.0;

masochism 36.0; obscene telephone calls 30.0; public masturbation 50.0; and bestiality 2.2.

Crossing Over

Initially, individuals suffering from a paraphilia were thought to be obsessed with one type of paraphilic behavior. Recent studies suggest that individuals with paraphilias may “crossover” from one paraphilia behavior to another. Of paraphilic persons primarily involved with actual touching of victims (frottage, rape, and pedophilia), 30.6% had previously or concomitantly been involved in paraphilic acts not involving touching of the victim (voyeurism and exhibitionism). Sixty-four percent of paraphilic individuals primarily involved with nontouching had previously or concomitantly carried out paraphilic acts that involved touching. Of paraphilic persons primarily victimizing outside the family, 29.4% had previously or concomitantly carried out paraphilic acts against family victims. Of those who primarily had been involved in paraphilic acts with family members, 65.8% had previously or concomitantly carried out paraphilic sexual acts against nonfamiliar victims. Of paraphilic persons who primarily committed acts against female victims, 22.9% had previously or concomitantly carried out paraphilic acts against male victims. Of those who had primarily carried out paraphilic acts against male victims, 62.6% had previously or concomitantly carried out paraphilic acts against female victims. Those paraphilias with the highest incidence of crossover were sadism, public masturbation, male incest pedophilia, fetishism, masochism, voyeurism, female nonincest pedophilia, exhibitionism, male nonincest pedophilia, transvestism, frottage, female incest pedophile, and rape of adult women. These studies suggest that paraphiliacs tend to cross over between touching and nontouching of their victims, between family and nonfamily members, between female and male victims, and to victims of various ages.

Comorbid Psychiatric Disorders

Studies have demonstrated high-comorbidity of general psychiatric disorders in paraphilic sexual offenders. The general psychiatric disorders comorbid with paraphilic sexual offenders include personality disorders, mood disorders, social anxiety disorders, substance use disorders, attention deficit hyperactivity disorder, and other neurodevelopmental disorders. The prevalence of general psychiatric disorders in paraphilic disordered, nonoffending patients is unknown. One study of 600 undergraduates with paraphilic interests by Watts and colleagues found narcissism, antisocial, and psychopathic features were most significantly associated with paraphilic interests.

ETIOLOGY

The etiology of paraphilias is unknown. Biologic theories, including neuroanatomical and neuroimaging studies of sex offenders, indicate that congenital or acquired brain damage is overrepresented. Some pedophilic perpetrators show structural impairment of brain regions critical for sexual development. Subtle defects of the right amygdala and closely-related structures might be implicated in the pathogenesis of pedophilia and might reflect developmental disturbances or environmental insults at critical periods. Neurologic hypotheses of paraphilia propose that sexual deviance is associated with frontal and/or temporal lobe damage. This damage may translate into an individual’s inability to control sexual impulses or directly cause paraphilic behavior because of tissue damage.

A monoamine hypothesis for the pathophysiology of paraphilic disorders was first articulated in 1997 by Kafka. This hypothesis was based on four converging lines of empirical evidence. First, the monoamine neurotransmitters dopamine, norepinephrine, and serotonin serve a modulatory role in human and mammalian sexual motivation, appetite, and consummatory behavior. Second, the sexual effects of pharmacologic agents that affect monoamine neurotransmitters can have both significant facilitative and inhibitory effects on sexual behavior. Third, paraphilic disorders appear to have Axis I comorbid associations with nonsexual psychopathologies that are associated with monoaminergic dysregulation. Last, pharmacologic agents that enhance central serotonergic function, in particular, have been reported to ameliorate paraphilic sexual arousal and behavior.

Psychoanalytical Theory

Psychoanalysts generally theorize that these conditions represent a regression to or a fixation at an earlier level of psychosexual development, resulting in a repetitive pattern of sexual behavior that is not mature in its application and expression. In other words, an individual repeats or reverts to a sexual habit arising early in life. Another psychoanalytic theory holds that these conditions are all expressions of hostility in which sexual fantasies or unusual sexual acts become a means of obtaining revenge for childhood trauma. The persistent, repetitive nature of the paraphilia is caused by an inability to erase the underlying trauma completely. Indeed, a history of childhood sexual abuse is sometimes seen in individuals with paraphilias.

Behaviorist Theory

Behaviorists suggest that paraphilias begin via a process of conditioning. Nonsexual objects can become sexually arousing if they are frequently and repeatedly associated with a pleasurable sexual activity. The development of paraphilia is not usually a matter of conditioning alone; there must usually be some predisposing factor, such as difficulty forming person-to-person sexual relationships or poor self-esteem.

The following are situations or causes that might lead someone in a paraphiliac direction:

- parents who humiliate and punish a small boy for strutting around with an erect penis;
- a young boy who is sexually abused;
- an individual who is dressed in a woman’s clothes as a form of parental punishment;
- fear of sexual performance or intimacy;

- inadequate counseling;
- excessive alcohol intake;
- physiologic problems;
- sociocultural factors;
- psychosexual trauma.

DIAGNOSIS AND CLINICAL FEATURES

DSM identifies eight categories of paraphilic disorders. All of the paraphilic disorders meet the following DSM criteria: The activity must be the sole means of sexual gratification for a period of 6 months and cause “marked distress or interpersonal difficulty” or “whose satisfaction has entailed personal harm, or risk of harm, to others” to be considered such. The categories of paraphilic disorders are exhibitionism, fetishism, frotteurism, masochism, pedophilia, sadism, transvestic fetishism, and voyeurism. Paraphilias that do not meet the guidelines of these categories are called a specific paraphilic disorder or unspecified paraphilic disorder. These terms replaced paraphilia NOS that existed in DSM-IV-TR. Paraphiliacs may choose an occupation or volunteer in an environment that places them in close contact with the desired object. For example, a pedophile may choose to volunteer with young children in an effort to make contact with children.

Diagnostic Considerations

The diagnosis of a paraphilic disorder is based on the individual’s report or demonstration of sexual arousal to a specified object or behavior with resultant impairment or risk of harm to self or others. For example, an individual with pedophilia may meet the diagnostic criterion by reporting sexual arousal to prepubescent children with a resultant psychological impairment such as anxiety or depression or having acted on the interests. Alternatively, a pedophile may meet the diagnostic criterion for pedophilia by demonstrating sexual arousal to stimuli of prepubescent children (e.g., erection to pictures of children in sexual poses) with a history of sexual contact with children. Paraphilic interests generally develop shortly after puberty and follow a chronic course with periods of variability in the degree of sexual interests, fantasies, or behaviors.

The diagnosis of a paraphilic disorder should be made after a comprehensive psychiatric evaluation, often referred to as a psychosexual evaluation. The clinical interview should include a general medical and psychiatric history to rule out medical conditions which may mimic paraphilias, such as treatment with dopaminergic agents or a history of traumatic brain injury. The sexual history should include a history of childhood exposure to sexual acts, sexual experiences, and sexual functioning, including masturbation patterns. A review of systems for each of the paraphilias is important as some individuals may present with multiple paraphilias.

Many individuals are reluctant to share sexual interests, fantasies, or behaviors due to shame or fears of legal consequences. Like all psychiatric disorders, it is important to obtain collateral data to inform diagnoses. When possible, obtaining a history of sexual behaviors from significant others is important. In addition, when an individual has legal involvement, reviewing police reports is imperative.

Exclusive and Nonexclusive Subtypes. Individuals who identify a paraphilic interest to be the only way to achieve sexual gratification are classified as “exclusive” paraphiliacs. A man who is only sexually aroused to prepubescent children is a pedophile, exclusive subtype. Individuals who have paraphilic interest but are able to derive sexual gratification from other experiences are called “nonexclusive” paraphiliacs. A nonexclusive pedophile experiences sexual gratification from both prepubescent children and adults. Nonexclusive paraphiliacs are more common than exclusive paraphiliacs.

Exhibitionistic Disorder

Exhibitionistic disorder, also known as “flashing” or “indecent exposure,” is qualified by recurrent and intense sexual arousal from the exposure of one’s genitals to an unsuspecting person persisting for a period of at least 6 months. In order to meet the criteria for a disorder, the individual must act on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. The diagnosis of exhibitionistic disorder describes individuals, who for at least 6 months, experience sexually gratifying urges, fantasies, or behaviors that are related to displaying nudity to an unsuspecting individual. Sexual arousal derives from the showing of one’s genitals, breasts, or buttocks to a nonconsenting individual. The diagnosis may be made if the sexual urges or fantasies lead to significant distress, impairment in functioning, or actual behavior.

Exhibitionism occurs predominately in men, with a peak age of onset in the 20s. In the United States, most exhibitionists are Caucasian males. About half of exhibitionists are married. The true prevalence is unknown, but the literature estimates a prevalence of 2% and 4%. Generally, no additional contact with the observer is sought; the individual is stimulated sexually by gaining the attention of and startling the observer. The exhibitionist often masturbates as part of the exposure. Exposing oneself while driving or in a public place is the most common expressions of exhibitionism. DSM-5 added specifiers to identify the source of sexual arousal. The specifiers include the following: sexual arousal by exposing genitals to prepubertal children, sexual arousal by exposing one’s genitals to physically mature individuals, and sexual arousal by exposing genitals to prepubertal children, and to physically mature individuals.

Exhibitionism is one of the three most common sexual offenses in police records (the other two are voyeurism and pedophilia). Exhibitionists have been found to have a high-rate of comorbidity among the paraphilias as a group and with other mental disorders. In other words, a patient in treatment for exhibitionism is highly likely to engage in other forms of deviant sexual behavior and to suffer from depression or an anxiety or substance abuse disorder. It should be noted, however, that exhibitionists are a heterogeneous group of individuals. The risk factors established in the literature include insecure attachment, childhood sexual abuse, substance abuse, and sexual dysfunction, which may not apply to all exhibitionists.

Fetishistic Disorder

Individuals who achieve sexual gratification from the use of nonliving objects or a highly specific focus on nongenital body parts over a period of at least 6 months with resultant clinically significant distress or impairment in social, occupational, or other important areas of functioning meet the criteria for fetishistic disorder. DSM-5-TR specifies that the fetish objects are not limited to articles of clothing used in cross-dressing or devices specifically designed for the purpose of tactile genital stimulation. Fetishistic disorder is further defined by specifiers indicating the source of sexual arousal such as “body part(s), nonliving object(s), or other.” The use of objects, most commonly women’s undergarments, shoes, stockings, or other clothing items, suffer from fetishism. Fetishists often collect the object of sexual gratification. Some of the more common objects are women’s lingerie or specific materials like silk, leather, or fur. Partialism, an older term, refers to fetishes specifically involving nonsexual parts of the body. Fetishism has predominantly been described in men and often exists with other paraphilias.

Fetishistic disorder is used to refer to at least a 6-month period of time in which an individual experiences sexual urges, fantasies, or behaviors related to objects, situations, or body parts not traditionally viewed as sexual. The sexual arousal must cause significant distress or impairment in functioning in order to be considered a paraphilic disorder. The true prevalence of fetishistic disorder is unknown because the literature is limited to case series. Most individuals with fetishistic disorder are male, and the most common fetish interest is feet. The etiology of fetishistic interests is unknown but likely includes biologic, developmental, and sociocultural factors.

Frotteuristic Disorder

The word “frotteur” derives from the French word “frotter,” meaning to rub. Frotteurism refers to the sexual gratification achieved by touching or rubbing against a nonconsenting person. In order to meet the criteria for frotteuristic disorder, the individual must experience recurrent and intense sexual arousal over a 6-month period, and either act on the behavior or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. This behavior often occurs in busy, crowded places, such as on busy streets or on crowded buses or subways. Frotteurism is predominantly described in men. A frotteur may fantasize that the woman he is rubbing up against is mutually aroused by the behavior.

The diagnosis of frotteuristic disorder is based on a greater than 6-month period of time in which an individual experiences gratification from urges, fantasies, or behaviors-related to brushing up against an unsuspecting individual. An individual meets the criteria for the diagnosis if he experiences significant distress or impairment in functioning as a result of the fantasies or has acted on the fantasies.

The true prevalence of frotteuristic disorder is unknown. The literature is limited to small samples without clear diagnostic criteria. The prevalence rates among these small studies range from 8% to 35%. The most common presentation is a male rubbing up against the breasts or genital area of a female in a crowded setting. The etiology of the disorder is not well-understood. Possible explanations for the behavior include psychoanalytic perspectives that the individual has unmet childhood needs met by rubbing up against an individual.

Pedophilic Disorder

Pedophilia has been included in the American Psychiatric Association DSM as a mental disorder since 1968. In DSM-III and DSM-III-R, pedophilia was defined as involving “recurrent intense sexual urges and sexually arousing fantasies involving sexual activity with a prepubescent child or children.” This criterion excluded individuals who molested children but did not experience recurrent intense sexual urges or fantasies involving sexual activity with a prepubescent child. DSM-IV-TR defined the diagnostic criteria for pedophilia as “recurrent, intense sexually arousing, fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children.” These fantasies, sexual urges, or behaviors are pedophilic if they “cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.” The pedophile also has to be 16 years of age or older and at least 5 years older than the victim child, although, for late adolescents, this age discrepancy is not specified. DSM-5 redefined pedophilia as pedophilic disorder, referring to the following criteria: over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger). The individual has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty. The individual is at least 16 years of age and at least 5 years older than the child or children. The disorder is further defined by specifying whether the sexual fantasies, sexual urges, or behaviors are the exclusive type, attracted only to children, or nonexclusive type, attracted to children and adults. Pedophilic arousal is further identified as sexually attracted to males, females, both, or and identified based on whether it is limited to incest.

The term *child molester* is a descriptive, nonclinical term. Some child molesters are driven by pedophilic interests, while others molest children as a result of nonpedophilic interests, such as the unavailability of an appropriate sexual partner. Pedophiles typically seek treatment as a result of legal consequences for illegal behavior.

For most pedophiles, the onset of attraction to children begins at the time of puberty or adolescence. The course of pedophilia is long-term. Individuals who engage in sexual activities with pubescent teenagers under the legal age of consent (ages 16 to 18) are known as *hebephiles* (attracted to individuals at the early stages of puberty) or *ephebophiles* (attracted to pubertal individuals). Most pedophiles do not use physical force to engage a victim in sexual contact; rather, they use manipulation and cajoling to elicit the desired response from the child. Pedophiles commonly justify and minimize the actions by stating that the child enjoyed the experience or that the experience was of educational value.

The majority of pedophiles are male. From federal data on sexual crimes, females were reported to be the molester in 6% of all juvenile cases. A study of 4,007 child molesters found 1% to be female, but the authors of this study suggested the number was low because of the systematic underreporting of women for molestation. Most pedophiles are nonexclusive, meaning that they have a sexual attraction to adults in addition to children. Pedophiles are categorized according to the type of exclusivity, gender of the child they are attracted to, and whether the child is familial (e.g., incest) or nonfamilial. A larger percentage of pedophiles are homosexual or bisexual in orientation to children. Individuals attracted to females usually prefer children between the ages of 8 and 10 years. Individuals attracted to males usually prefer boys between the ages of 10 and 13 years.

Fifty percent to seventy percent of pedophiles can be diagnosed as having another paraphilia, such as frotteurism, exhibitionism, voyeurism, or sadism. Pedophiles are approximately two and a half times more likely to engage in physical contact with a child than simply voyeuristic or exhibitionist activities. Typically, pedophiles engage in fondling and genital manipulation more than intercourse, with these three exceptions: intercourse occurring in cases of incest, occurring in pedophiles with a preference for older children or adolescents, and occurring when children are physically coerced.

The question of whether individuals who view child pornography meet the criteria for pedophilic disorder and are at risk for committing hands-on sexual offenses has been the focus of research. Research has not established a clear relationship between viewing child pornography and child sexual offenses. Studies show the majority of men convicted or charged with child pornography offenses have demonstrated sexual arousal to prepubescent stimuli on phallometric testing.

Although preliminary, imaging techniques such as functional magnetic resonance imaging (fMRI) have attempted to identify variations in brain morphology in individuals with pedophilia. fMRI in combination with emotional and/or sexual stimuli showed pedophilia is likely associated with altered brain activity, particularly in the frontal brain areas and the temporal lobe.

Research into the etiology of pedophilia has been inconclusive. Reported differences between pedophiles and the general population include lower intelligence, a slight increase in the prominence of left-handed individuals, impaired cognitive abilities, neuroendocrine differences, and brain abnormalities, particularly frontocortical irregularities or differences.

Pedophilic disorder refers to the sexual gratification for at least a 6-month period of time from sexual fantasies or behavior related to sexual activity with a prepubescent individual. In order to be considered pedophilic, the individual must be at least 16 years old, and the prepubescent child must be at least 5 years older than the individual. The diagnosis is made when the individual's ongoing sexual urges or fantasies have led to significant distress, impairment in functioning, or actual behavior. The true prevalence of pedophilic disorder is unknown. Studies examining pedophilic interest, not the disorder, show prevalence rates ranging from 2% to 24%, depending on the sample. Research of men convicted of child sexual abuse found that half did not meet the criteria for pedophilic disorder.

Sexual Masochism Disorder

Sexual masochism is a term used to refer to sexual gratification produced by pain that is inflicted by others or by one's self. Sexual masochistic disorder refers to, over a period of at least 6 months, recurrent and intense sexual arousal from the act of being humiliated, beaten, bound, or otherwise made to suffer from resultant clinically significant distress or impairment in social, occupational, or other important areas of functioning. Studies suggest that an estimated 5% to 10% of the population has engaged in some masochistic sex play. Research suggests that sexual masochism is a fairly benign activity. Studies of practicing masochists have found them to be reasonably well-adjusted, successful individuals. If studies describe sexual masochism as a benign activity, is sexual masochism a mental disorder? Proponents of sexual masochism as a mental disorder theorize that an individual may become dependent on masochistic activity or may engage in dangerous or injurious behavior warranting a pathologic aspect of the behavior. In most cases, masochism does not cause harm to individuals. However, sexual masochism disorder with asphyxiophilia, which refers to the practice of achieving sexual arousal derived from the autoerotic restriction of airflow, can cause accidental death. There is no scientific evidence to support the diagnosis of sexual masochism as pathologic. Therefore, if an individual seeks treatment for masochism and there is no harm caused by the behavior, the individual will not benefit from treatment.

Sexual masochism is one of the few paraphilias described in women. As discussed previously, the majority of paraphilias are almost never diagnosed in women. The three main characteristics of masochism are pain, loss of control, and humiliation. One of the psychodynamic theories postulated about masochism is Freud's writings that masochism is derived from sadism: More precisely, the person wishes to dominate and hurt others, but this desire gives rise to guilt, so the person defensively converts it into its opposite, namely a desire to submit to domination by others. However, this theory is not entirely supported by empirical evidence.

Sexual masochism disorder refers to at least a 6-month period of time with ongoing sexual arousal from fantasies, urges, or behaviors related to the physical or psychological abuse one is made to suffer. The sexual urges or fantasies cause significant impairment in functioning, significant distress, or actual behaviors. The true prevalence of sexual masochism disorder is unknown. Studies examining sexual, sadomasochistic interests in nonclinical populations reveal the behavior as fairly common. The prevalence, however, of masochistic disorder has not been adequately studied.

Sexual Sadism Disorder

Sexual sadism is sexual gratification achieved from the infliction of psychological or physical suffering or both on a partner. Sexual sadism disorder is a period of at least 6 months with recurrent and intense sexual arousal from the physical or psychological suffering of another person, and the individual has acted on these sexual urges with a nonconsenting person or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Sadists experience sexual fantasies involving the suffering of another as well as compulsions to enact fantasies. The sadist's partner may consent to the behavior in an effort to satisfy their own masochistic fantasies, or the partner may be the victim. Sadism, like masochism, has been described in both men and women. Similarly, both sadism and masochism are sexual behaviors that are reported in the context of normal sexuality.

Krafft-Ebing subclassified sexual sadism into several categories, including:

1. Lust-murder;
2. Mutilation of corpses or necrophilia;
3. Injury to females (stabbing);
4. Defilement of women;
5. Other kinds of assaults on women—symbolic sadism in which, for example, the perpetrator cuts the hair of his victims rather than harming them directly;
6. Ideal sadism or sadistic fantasies alone without acts;
7. Sadism with other objects, for example, whipping boys;
8. Sadistic acts with animals.

In some individuals, sadistic fantasies and compulsions lead to rape or homicide. However, not all rapes or sexual homicides are perpetrated by sadists. Sadistic rapists are aroused by the use of gratuitous violence, whereas the preferential rapist is thought not to use greater force than is necessary for the submission of the victim. The sadistic rapist is detected by demonstrating a higher level of arousal to a description of physical but nonsexual assault on female victims when subject to phallometric assessment. One confounder, however, is that normal men acknowledge sexual arousal to the idea of raping or hurting a woman. Among the general male population, 30% report fantasies of tying up and raping a woman.

The majority of sadists report the onset of fantasies in their late teen years. Some sadists' accounts of sexual arousal to violence are based on an association between excitement and punishment in childhood. However, the majority of sadists are unable to delineate a historical marker for the sadistic sexual appetite.

The diagnosis of sexual sadism disorder is used to define a period of at least 6 months of sexual gratification from fantasies, urges, or behaviors related to the harm of a nonconsenting individual by psychological abuse or physical abuse. The diagnosis is made when the individual has acted on the fantasies or experienced sexual fantasies or urges that cause significant distress or impairment in functioning. The true prevalence of sexual sadism disorder is unknown and varies depending on the sample studied. A prevalence rate ranging from 2% to 30% has been reported in forensic samples.

Transvestic Disorder

The literal meaning of the word transvestism is to wear the clothing of the opposite sex. DSM-5-TR uses the term transvestism to refer to a male who dresses in women's clothing with resultant sexual arousal. Transvestic disorder is defined as the recurrent and intense sexual arousal from cross-dressing for over a 6-month period of time in which the fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. If the cross-dresser is specifically sexually aroused by fabrics, materials, or garments, the specifier "with fetishism" should be added. Cross-dressing typically begins in prepubertal children but does not appear to have a sexual component until late adolescence or early adulthood. Individuals with transvestic disorder are usually heterosexual. However, there is a subgroup of men with transvestic disorder who report gender dysphoria, which can be defined as discontent with one's biologic sex, the desire to possess the body of the opposite sex, and the desire to be regarded by others as a member of the opposite sex. Initially, the presence of gender dysphoria ruled out the diagnosis of transvestic disorder according to DSM-5-TR. However, additional research suggests the presence of gender dysphoria is not exclusionary in the diagnosis of transvestic disorder. DSM-5-TR specifier "with autogynephilia" refers to individuals who are sexually aroused by thoughts or images of self as a female. Autoandrophilia is used to refer to sexual arousal to the thought or image of oneself as male.

It is unclear whether transvestism causes the level of dysfunction typical of mental disorders. Clinical evidence suggests that transvestic disorder impairs the ability to form intimate pair bonds with other persons in the sense that relationships tend to break down because the individual with transvestic fetishism often has more interest in the nonhuman aspects of the partner (e.g., clothing). However, not all cases of transvestism exhibit dysfunctional relationships or distress.

The diagnosis of transvestic disorder describes a period of at least 6 months of ongoing sexual arousal from sexual fantasies, urges, or behaviors-related to dressing in the clothing of the opposite gender. Sexual arousal results in significant distress or impairment in functioning. The true prevalence of transvestic disorder is unknown. In nonclinical samples, 3% of men and 0.4% of women describe one or more incidents of transvestic fetishism. The prevalence of transvestic disorder in clinical populations is unknown.

Voyeuristic Disorder

Voyeurism is sexual gratification achieved from watching people undressing or nude or observing them during sexual acts without their knowledge or consent. Voyeuristic disorder is qualified by recurrent and intense sexual arousal from observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity over a period of at least 6 months. In addition, to meet the criteria for voyeuristic disorder, the individual is at least 18 years of age and has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Voyeurs are usually men in their 20s or 30s who prefer to watch unknown women. They may masturbate while observing the victims but typically seek no contact with the victim. Some voyeurs report sexual fantasies that the woman they are watching will solicit sex from them. The onset of voyeuristic behavior is usually before the age of 15 years. Voyeurs tend to have multiple paraphilias and to cross over from one paraphilia to another. Although some voyeurs do not commit more serious paraphilic acts, there are some suggestions in the literature that serial rapists and murderers began with histories of voyeurism. Voyeurism is one of the least understood behaviors of paraphilias.

The diagnosis of voyeuristic disorder refers to a 6-month period of ongoing sexual gratification from observing an unsuspecting individual who is undressing, naked, or engaging in sexual activity. In order to meet the diagnostic criterion for the diagnosis of voyeuristic disorder, an individual must be at least 18 years old and either engaged in the actual behavior or experienced significant distress or impairment in functioning as a result of the specific sexual arousal. The true prevalence of voyeuristic disorder is unknown. Nonclinical studies of paraphilic interests rate voyeurism and frotteurism as the most popular. In these studies, both men and women report voyeuristic interests at the rate of 12% in men and 4% in women. Lower satisfaction with life, substance use, high sexual interest, more sexual partners, and psychological problems are associated with voyeuristic behaviors.

PATHOLOGY AND LABORATORY EXAMINATION

Diagnostic Tests

The diagnosis of a paraphilic disorder is made based on data gathered during the psychiatric evaluation. There is no definitive test for paraphilic disorders. Psychological testing is not helpful in such diagnoses. Objective tests of sexual interests may be helpful in identifying sexual interests. Objective tests include sexual history polygraphs, visual reaction time tests, and penile plethysmography (phallometric testing). Polygraphs are not routinely used in the clinical setting but are more common in mandated sex offender treatment. Visual reaction time tests identify sexual interest based on the amount of time an individual views images of males and females of various ages.

Plethysmography is the phallometric assessment of physiologic sexual arousal by use of equipment that measures penile circumference in males. The test is conducted by placing a small circular strain gauge around the penis. This gauge is calibrated to measure changes in the circumference of the penis. The test subject is shown both audio and visual stimuli depicting various sexual vignettes. As the individual becomes aroused by the stimuli, the erect penis displaces the gauge, and a measurement is recorded. Phallometric testing helps elucidate an individual's sexual interest without depending on self-disclosure. One of the difficulties working with individuals who have paraphilias is the individual's reluctance to report his sexual interests.

Objective testing is one way of addressing the difficulty of self-disclosure in paraphiliacs. In addition to diagnostic evaluations, objective testing is helpful in determining an individual's response to treatment.

DIFFERENTIAL DIAGNOSIS

The diagnosis of a paraphilia begins with the identification of the individual's sexual interest. It is important to understand an individual's sexual preference before the diagnosis of paraphilia can be made. One of the common errors made in the area of paraphilias is to make a diagnosis based on an individual's behavior rather than on the individual's sexual preference. For example, the differential diagnosis for a child molester may include pedophilia, personality disorder, mental retardation, or substance abuse. In order to determine what diagnosis fits the child molester, one has to understand what motivated the molester to have sexual contact with the child. If the molester describes sexual urges and fantasies of sexual contact with a prepubescent individual, they meet the criteria for pedophilia. However, if the molester reports a history of learning difficulties consistent with intellectual disability and explains his molesting behavior as his desire to "have sex with anyone," the diagnosis is an intellectual disability and possibly personality disorder. The differential diagnosis of paraphilias is simple if one understands what the sexual motivations of the subject are.

Like all psychiatric symptoms, it is important to determine if sexual behaviors or fantasies are better explained by a general, nonparaphilic disorder. For example, an individual who presents with variable sexual interests in the setting of psychosis or mood episodes may not meet the criteria for a paraphilic disorder. The clue to a nonparaphilic presentation is the emergence of sexual interests later in life in settings of psychiatric decompensation. Paraphilic interests may wax and wane but rarely develop late in life. Medical conditions such as traumatic brain injuries, cerebrovascular accidents, and neurodegenerative syndromes such as Huntington disease may present with new-onset sexual symptoms. Dopaminergic agents have also been associated with hypersexuality and other paraphilic symptoms.

COURSE AND PROGNOSIS

Paraphilic behaviors emerge in adolescence and early adulthood. In general paraphilic behaviors are chronic. Although it has been shown that individuals may cross over from one paraphilia to another, the overall course of paraphilic behavior is chronic. Because of the early onset and repudiated biologic priming of the paraphilias, they are often difficult to treat.

TREATMENT BACKGROUND

The efficacy of treatment in paraphiliacs is unknown. Empirical evidence for the treatment of individuals with paraphilias is derived from studies of sex offenders. Although studies comparing treated and untreated sex offenders have been done, measurement of outcome is flawed, with recidivism rates underestimating actual recurrence of the problematic behavior. Methodologic challenges such as sample selection, study design, and assessment of outcome represent significant problems in treatment efficacy studies. The majority of treatment efficacy studies are conducted on incarcerated or civilly committed offenders. Those individuals who are incarcerated or civilly committed represent a unique population with treatment outcomes that may not generalize to the nonincarcerated or community-residing sex offender. Many studies do not differentiate between types of offenders. For example, a study that evaluates child molesters may not differentiate between intra- and extrafamilial offenders. Research suggests that incest offenders recidivate at approximately half the rate of extrafamilial child molesters.

A well-designed study of treatment efficacy in sex offenders would compare treated offenders with a matched, randomly assigned control group. However, the ethical and public safety implications of such a study impede its design. Sex offenders are extremely heterogeneous, and when this is not recognized, it is very difficult to make comparisons among treatment efficacy studies.

Biologic Treatment

The scientific basis of biologic treatment in paraphiliacs is the reduction of sexual behaviors by decreasing testosterone levels. Testosterone is a steroid hormone produced by the testes that are responsible for the development of secondary sex characteristics in men. Testosterone helps maintain sex drive, the production of sperm cells, male hair patterns, muscle mass, and bone mass. Testosterone strongly influences both male and female sexual drive and the resultant sexual behavior. Animal studies show that male copulatory behavior is almost entirely dependent on circulating levels of plasma testosterone.

The production of testosterone is mediated by FSH and luteinizing hormone (LH), two hormones produced by the pituitary gland. LH signals the testes to produce testosterone. The hypothalamus senses whether the production of testosterone is too much or too little. If the testes are producing too little testosterone, the hypothalamus secrets a hormone called GnRH, which signals the pituitary to increase production of LH, which results in an increase in testosterone production. If the testes are producing too much testosterone, the hypothalamus secretion of GnRH is inhibited. This process, whereby the hypothalamus modulates the production of testosterone, is called negative inhibition.

Surgical Treatment

Surgical treatment for sex offenders consists of two types: neurosurgery and castration. The neurosurgical procedure involves stereotaxic removal of parts of the hypothalamus to disrupt the production of male hormones and decrease sexual arousal and impulsive behaviors. This procedure had significant adverse effects and was considered largely ineffective. Surgical castration is the removal of the testes. The effect of surgical castration is to globally reduce available androgens by the removal of the testes. Sturup followed 107 castrated sex offenders and compared them to 58 who were not castrated over a period of 18 years. The castrated individuals recidivated at a rate of 4.3%. The 58 uncastrated individuals recidivated at a 43% rate. Postcastration follow-up studies provide the most comprehensive outcome data on the effect of reducing plasma testosterone and the resultant suppression of the sexual drive and deviant sexual behavior. These studies have reported recidivism rates of less than 5% with follow-up periods of up to 20 years in a large sample size.

The introduction of antiandrogen and hormonal medications has rendered surgical castration nearly obsolete. The effects of surgical castration can be achieved through chemical castration (i.e., the use of medications to decrease testosterone production) without the invasiveness and irreversibility of surgery. Some states in the United States, such as Texas and California, mandate chemical or surgical treatment of dangerous sexual offenders. Controversy exists as to whether surgical castration should be offered as a treatment, as chemical castration achieves the same results and spares the procedure.

Pharmacologic Treatment

Antiandrogens. Androgens are male sex hormones that promote the development and maintenance of male sex characteristics. Testosterone is the most common androgen in man. Antiandrogen treatment refers to treatment with drugs used to block the production or interfere with the action of male sex hormones. Cyproterone acetate (CPA; Androcur) and medroxyprogesterone (MPA; Depo-Provera) are the two most commonly used antiandrogen medications. CPA is not available in the United States but is widely available in

Canada and Europe. Both CPA and MPA are synthetic progesterone that reduce the serum level of testosterone. Reduction of testosterone has been shown to reduce libido, erections, ejaculations, and spermatogenesis. The World Federation of Societies of Biological Psychiatry (WFSBP) concluded in their guidelines for the biologic treatment of paraphilias with MPA that there is minimal research-based evidence to support this recommendation. They also reported severe side effects observed with MPA, concluding that the benefit/risk ratio did not favor the use of MPA. WFSBP similarly concluded that there is minimal research-based evidence to support treatment with CPA.

The risks associated with the use of antiandrogen agents include side effects such as weight gain, hyperglycemia, hot, and cold flashes, liver dysfunction, hypertension, muscle cramps, phlebitis, gastrointestinal complaints, and feminization. In addition, there is little known about the long-term sequelae of antiandrogen treatment. The majority of antiandrogen studies follow patients for 8 years or less. The patient who agrees to antiandrogen treatment should be educated about the absence of long-term data.

Hormonal Agents

Leuprolide (Eligard) and triptorelin (Trelstar) are hormonal agents referred to as long-acting GnRH agonists. These agents inhibit the secretion of LH with a resulting decrease in plasma testosterone levels and libido. They produce a chemical castration in that the hypothalamic–pituitary axis is exhausted, and there is a potent inhibition of gonadotropin. A meta-analysis conducted by WFSBP concluded that there were no controlled studies, and some biases were observed. However, the efficacy observed in these open studies was very high, and in most cases, subjects were previously treated with psychotherapy or other antiandrogens without efficacy. The WFSBP reported that despite the lack of controlled studies, the efficacy of hormonal agents was observed in open studies in patients with treatment-refractory and or severe paraphilic disorders. A Cochrane analysis of testosterone-lowering medications concluded that the efficacy of such medications was uncertain and that further research was necessary.

The side effects associated with GnRH agonists include decreased bone mineral density or osteopenia, weight gain, hyperglycemia, diabetes, hypertension, and insomnia. The most commonly reported side effects are erectile/ejaculatory problems and gynecomastia. In general, patients reported fewer side effects on GnRH agonists when compared to antiandrogens. The preliminary studies of GnRH agonists suggest that leuprolide and triptorelin may be more effective, better-tolerated alternatives to antiandrogen treatment.

Selective Serotonin Reuptake Inhibitors

Although the pharmacologic mechanism is poorly understood, SSRIs have been shown to be effective in reducing paraphilic symptoms. Animal models showed that decreased serotonin levels increased sexual appetitive behaviors while enhanced central serotonin activity reduced them. Clinical observations of the similarities between paraphiliac fantasy urges or behaviors with obsessive-compulsive symptoms led to hypotheses that SSRIs may be efficacious in paraphilias as they have been in OCD. Case reports have reported the positive effects of SSRIs in the treatment of paraphilias. Most of the studies examining the efficacy of SSRIs in paraphilias are case reports or small sample sizes and do not include placebo-controlled double blinds studies. The WFSBP published the Guidelines for the biologic treatment of paraphilias in 2010 and again in 2020. These guidelines conclude that “a critical analysis of all studies that involved the use of SSRIs in the treatment of paraphilias concluded that the results of psychotropic drug interventions are not favorable.” In summary, although data exist to suggest that SSRIs are effective in the treatment of paraphilias, presently, there are insufficient data to conclude that SSRIs are equally efficacious as antiandrogens or hormonal agents.

Other psychotropic medications, including anticonvulsants, lithium, and tricyclic antidepressants, have not been shown to be efficacious in paraphilic disorders.

The WFSBP has proposed an algorithm for the pharmacologic treatment of paraphilic disorders. This algorithm assigns treatment based on the level of severity of the paraphilia. The less severe paraphilias are treated with psychotherapy, while the more severe paraphilias add biologic treatment starting with SSRIs and moving to testosterone-lowering medications.

Psychological Treatment

Psychological approaches to the treatment of sexual offenders focus on direct treatment approaches to modify offenders' cognitions and attitudes. Cognitive approaches described the concept of cognitive distortions (minimizations, excuses, justifications) as one factor that may maintain offender behavior. Relapse prevention and the sexual assault cycle are theoretical models purporting to describe the cognitions and behaviors of sex offenders before, during, and after their abusive acts. Relapse prevention models of treatment were the mainstay of treatment for many years. However, in the past decade, these models have largely been abandoned for strength-based rehabilitation programs. The two most common strength-based rehabilitation programs that are currently employed in sex offender treatment are the Good Lives Model, and the Risk Need Responsivity Model. Research has consistently demonstrated that structured behavioral or cognitive-behavioral treatment designed to address offending behavior is more effective in reducing reoffending than didactic, experimental, nondirective, or psychodynamic modes of treatment.

Current sex offender treatment programs have focused on identified dynamic risk factors for sexual offending. These treatment programs are adopted for the treatment of paraphilic disorders since evidenced-based psychological treatments for nonoffending paraphiliacs do not exist. These risk factors, which serve as the focus of treatment, include the following: insecure attachments, lack of intimacy, emotional loneliness, poor self-regulation, sexual preoccupation, deviant sexual interest, emotional congruence with children, lack of concern for others, attitudes supportive of offending women, or hostility toward them. Treatment efficacy has also been measured as it relates to the qualities of the therapist. Therapists who are nonjudgmental and empathic deliver the most effective treatment regardless of the orientation of the treatment program.

Recidivism rates from cognitive and behavioral treatment programs range from 3% to 31%, depending on the study. A meta-analysis found that cognitive-behavioral treatment and antiandrogen treatment were comparable in their treatment effects and significantly more effective than behavioral treatment alone.

MODELS OF TREATMENT

The treatment of individuals with paraphilias and sex offenders has primarily focused on two areas: Cognitive-behavior group treatment and pharmacologic treatment. Treatment programs target risk factors empirically associated with sexual offending and recidivism. Meta-analysis has shown that cognitive-behavioral treatment is most effective in reducing sex offender recidivism. Treatment models have changed over the years as research in the field of sex offender management has evolved. Currently, cognitive-behavioral treatment remains the most widely accepted and empirically supported model of sex offender treatment. Best practices include the use of actuarial tools and data-driven instruments in the determination of risk. Research demonstrates that actuarial methods are consistent in predicting the relative risk of sex-offending behavior and are considered more accurate than unstructured professional judgment. A research query asking sex offenders in treatment about acceptable types of treatment revealed the preferred therapies were individual psychotherapy, social skills training, and group therapy, whereas aversion conditioning, castration, and sex drive-reducing drug therapy were the least acceptable forms of treatment.

ETHICAL AND LEGAL CONSIDERATIONS

The legal and ethical issues that arise in the course of sex offender treatment are unique to this population. As such, the traditional codes of ethics employed in medical treatment are not applicable to the treatment of sex offenders. A significant percentage of sex offenders receiving treatment have been mandated by the courts to do so as part of sentences of incarceration or release into the community. The concept of mandated or involuntary treatment raises the issue of whether informed consent is possible in sex offender treatment. A condition of informed consent for medical treatment is that the consent must be voluntary. Obviously, court-ordered sex offender treatment is not voluntary. Individuals who reject treatment are subject to punishment imposed by the courts. Individuals who have been court-ordered to receive treatment do not have a choice regarding the type of treatment or the treatment provider. Sex offenders are required to complete particular programs, irrespective of any other treatment they might be receiving, in order to gain community release or avoid imprisonment.

In the medical model, patients have a right to refuse various types of treatment. The right to refuse treatment is based on an individual's constitutional right to privacy. The court views sex offenders as incompetent patients, and as such, the court becomes the decision-maker regarding treatment.

Confidentiality and Privilege

Confidentiality refers to the physician's obligation to keep information learned in a professional relationship private from other parties. Privilege refers to the patient's right to prevent a physician from providing testimony about personal medical information. Both confidentiality and privilege are routinely breached in sex offender treatment. When individuals enter treatment, they are required to give permission for their cases to be discussed with both clinical and nonclinical personnel, correctional officers, members of their family, past and potential victims, and those associated with them and fellow offenders.

In response to the deviations from traditional ethical codes inherent in sex offender treatment, ethical and practice guidelines were developed by the association for the treatment and prevention of sexual abuse (ATSA). ATSA's code of ethics endorses standards of professional conduct that promote competent practice, and as such, they represent a public commitment to clients and society toward the goal of preventing sexual violence. The ATSA guidelines state that the ethical care of sex offenders is achieved by encouraging individuals to take responsibility for their behavior, that is, admission of guilt. ATSA maintains that the identification and collaborative management of risk and safety factors are indeed in the best interests of both sex offender patients and potential victims due to the grave consequences incurred by sexual offender recidivism.

Castration of Sex Offenders

In 1996, California became the first state to authorize the use of either chemical or surgical castration for certain sex offenders who were being released from prison into the community. To date, an additional eight states authorize surgical or chemical castration for sex offenders, including Georgia, Montana, Oregon, Wisconsin, Florida, Iowa, Louisiana, and Texas. The APA stated that “these laws, which predicate release from prison on chemical castration by surgery or antiandrogenic agents, are objectionable because they are not based on adequate diagnostic and treatment considerations. They also improperly link medical treatment with punishment and social control.” In some states, informed consent for the procedure is not required. In other states, informed consent requires only that the offender be informed regarding the side effects.

FUTURE DIRECTIONS

Further Research

Although studies have demonstrated the effectiveness of some modalities of sex offender treatment, the scientific literature does not identify a definitive effective treatment. The literature suggests that both cognitive-behavioral therapies and antiandrogen medication decrease sex offender recidivism. A decrease in sex offender recidivism, however, does not translate to a decrease in paraphilic behaviors. However, the current sex offender legislation in the United States is not based on the literature. Rather the legislation focuses on the preventive detention of sex offenders without concurrent evidence-based sex offender treatment. The future of research in the treatment of sex offenders and paraphilias lies in the development of evidence-based knowledge that will inform both clinical decisions and public policy. This effort may be afforded by interdisciplinary collaboration between the scientific community, correctional professionals, and policymakers.

Specialized Training

Many psychiatrists are unfamiliar with the fundamentals of the assessment and treatment of individuals with paraphilias. The advent of laws for the civil commitment of sex offenders has resulted in the need for psychiatrists trained in paraphilias. As a result of sex offender legislation, the treatment and release decisions regarding sex offenders have become a focus of attention for psychiatry. Forensic psychiatrists or psychologists must render an opinion as to whether the sex offender has a diagnosed mental disorder and, as such, represents a risk to public safety if released from custody into the community. In order to provide competent care to individuals with paraphilias, psychiatrists should be educated about the evidence-based approach to the treatment and evaluation of this population.

Education of the Public

The general public perceives sex offenders as a homogeneous group of offenders who are not treatable. However, recent meta-analyses have demonstrated that sex offenders are a highly heterogeneous population with different rates of reoffending and responsiveness to treatment. The successful treatment of sex offenders is dependent, in part, on the support of the public and the courts. In order to implement an evidence-based treatment, the offender must be afforded the opportunity for treatment. The opportunity for treatment is created by an informed society that legislates treatment that is informed by scientific evidence. The education of the public is integral to the successful treatment of sex offenders.

21.4 Gender Identity, Gender Diversity, Gender Dysphoria/Incongruence

Jack Drescher, M.D., and William M. Byne, M.D., Ph.D.

Variations of gender expression have been documented throughout history, in myth, literature, and in actual practice. Starting in the 19th century, gender-diverse presentations became a subject of medical and psychiatric interest. Nonconforming expressions of gender were initially conflated with and labeled as “homosexuality.” However, by the mid-20th century, the modern concept of gender identity was teased out from that of sexual orientation (see homosexuality 21.2). After that happened, diagnoses of “transsexualism” and “gender identity disorder” began to appear in diagnostic manuals, along with homosexuality.

With the publication of the fifth edition of the Diagnostic and Statistical Manual (DSM-5) in 2013 and its text revision (DSM-5-TR) in 2022, a less stigmatizing diagnosis of *gender dysphoria* (GD) replaced *gender identity disorder* (GID). In the 11th edition of the International Classification of Diseases and Related Health Problems (ICD-11), *transsexualism* was replaced by *gender incongruence* (GI), and, for the first time, the diagnosis was moved out of the ICD Mental Disorders section. These diagnostic changes came amidst a growing social acceptance of gender-diverse and transgender individuals, which led to a rethinking of early psychopathologizing theories and formulations about them.

In recent years, however, the subject of what exactly constitutes socially acceptable expressions of a person’s gender identity has become a subject of popular interest, debate, and concern. Most troubling, the issue has been increasingly politicized in the forms of “bathroom bills,” laws intended to prevent transgender individuals from using restroom facilities that accord with their gender identity; proposed and enacted legislation making it a felony for clinicians to provide medical treatment to transgender minors; and laws prohibiting transgender youth from playing on high school sports teams that accord with their gender identity and expression.

In other words, questions have been raised not only about what constitutes appropriate expressions of gender but also who ultimately is responsible for deciding what is and is not appropriate: Psychiatrists? Religious authorities? Civil rights and human rights advocates? Complicating matters further, not all cultures endorse *binary* notions of gender constituted simply of "men" and "women," Native American "two-spirit people" *(berdache)* or *hijras* of India being notable examples. In the context of cultural shifts in contemporary discussions of gender, this chapter attempts to provide a more expansive view of gender diversity and gender identity in addition to discussing psychiatric aspects of diagnosing GD/GI and its treatment.

DEFINITIONS

Although *sex* and *gender* are often used interchangeably, *sex* refers to the status of biologic variables that can be described as either male-typical or female-typical in normatively developed individuals (e.g., genes, chromosomes, gonads, internal and external genital structures). Prior to the mid-1950s, the word *gender* had been employed primarily to refer to classes of nouns in languages; however, John Money and his colleagues introduced the concept of *gender* in reference to attributes of people; specifically, those attributes that are associated with the sex assigned at birth but not necessarily determined by it. For example, they observed that most individuals born with somatic variations of sex development (historically referred to as hermaphroditism, pseudohermaphroditism, and intersex conditions but now referred to as disorders/differences of sex development (DSD) often live and think of themselves as males or females according to the sex they were assigned by physicians and parents in infancy and independent of the status of any particular genetic, endocrinologic, or physical variable of sex.

Gender, therefore, came to refer to the social categories of males (i.e., boys, men) and females (girls, women) as well as to factors related to living in the social role of a man or a woman. More recently, however, sex and gender tend to be interpreted synonymously in medicolegal contexts. The sex initially assigned to individuals with a DSD is referred to as their *sex assigned at birth* (or *gender assigned at birth*), a term which has increasingly been used to refer to the sex/gender initially assigned to all individuals, but particularly in discussing the developmental histories of transgender individuals. Another common term in the literature, *natal gender,* whose usage has fallen out of favor in recent years, was interchangeable with both *sex* and *gender assigned at birth.*

Gender identity, a term first coined by psychoanalyst Robert Stoller in the mid-20th century, came to signify one's persistent inner sense of belonging to either the male or female gender category. Today, there are other recognized categories of gender identity that are neither male nor female. In earlier times, from a more binary perspective, John Money defined *gender role* as those things a person says or does to disclose themselves as having the status of boy or man, girl or woman, respectively (e.g., general mannerisms, mode of dress, interests, pastimes, deportment, and demeanor; spontaneous topics of talk in unprompted conversation and casual comment). *Gender role* was conceptualized as the outward expression of the inner sense of *gender identity.* However, the terms *experienced gender* and *expressed gender,* respectively, have increasingly replaced gender identity and gender role, particularly in the legal and political arenas concerned with antidiscrimination protections. Again, although initial descriptions of gender role and identity implied two discrete gender categories, gender is increasingly regarded as more *fluid,* reflecting either a continuous dimension or even a mosaic of masculinity/femininity as opposed to a dichotomy of masculine and feminine. Thus, gender identity/experienced gender may be described as male (boy/man), female (girl/woman), somewhere in between, some combination of both, or neither. Gender role/expressed gender may be described as masculine, feminine, or nonbinary. Complicating matters further, notions of what constitutes *masculine* or *feminine* vary across individuals, cultures, and times.

Transgender is a popular term coined by Virginia Prince in the early 1970s, referring to people who lived full time in a gender that was not the one that usually went with their genitals. In recent decades, it has become an umbrella term that usually refers to someone whose gender identity or gender expression and gender assigned at birth are discordant or not conforming to stereotypical social norms. Being transgender may be associated with a desire to transition to or live as a gender different from the gender assigned at birth. Other identities could include *genderqueer, gender nonconforming (GNC), bigender, nonbinary, two-spirit,* or *eunuch*. In recent years, there has been a public proliferation of gender identities. In addition, members of the transgender community have coined the term *cisgender* (based on the concept of cis/trans isomerism in organic chemistry) as a way to describe nontransgender individuals whose gender identity and birth-assigned sex are in alignment. Some cisgender people publicly embrace this identity, but many simply think of being cisgender as "normal."

The concepts of changing the sexual characteristics of the body and transitioning gender role date back several millennia, notably found in the Greek myth of Tiresias, who was born with the body of a man but changed by the goddess Hera into a woman for 7 years. Of more recent historical vintage, the protagonist of Virginia Woolf's novel *Orlando* goes to sleep as a man and inexplicably wakes up as a woman. Today, modern medical and surgical practices, as well as changing social mores, have shifted the prospect of changing the sexual appearance of one's body from a subject of mythology and fiction to a highly specialized clinical reality. Historically, the term *transsexual* referred to an individual who employed hormonal and/or surgical means to modify the body, so it conformed to their experienced gender. In that nosology, someone who had both gender-affirming hormonal as well as bottom and top surgical treatments was said to have made a *complete transition.* An individual who had only hormones or only surgery was said to have had a *partial transition.* An individual assigned male at birth who transitioned to live as a woman was called a male-to-female (MTF) individual, an MTF transsexual or, in contemporary language, a *transgender woman, a transwoman, or woman of transgender experience.* An individual assigned female at birth who transitioned to live as a man was called a female-to-male (FTM) individual, an FTM transsexual, or, again in today's terminology, *a transgender man, transman,* or *man of transgender experience.*

Historically referred to as *sex reassignment surgery,* more recently, these surgical transition procedures have been referred to as *gender reassignment surgery*, *gender confirmation surgery, and most gender-affirming surgery (GAS).* Because this chapter addresses surgeries done in the context of affirming the experienced gender identities of adolescents and adults, this chapter uses GAS in reference to these procedures. Surgical options include *top surgery* (breast augmentation for transgender women, mastectomy, and male breast construction for transgender men) and bottom surgery (gonadectomy and genitoplasty for transgender women, genitoplasty, gonadectomy, and hysterectomy for transgender men). Transgender women often undergo facial electrolysis, while some transgender individuals elect surgeries for facial and voice feminization or masculinization. Some individuals may not desire to undergo all of these surgical procedures, while financial or medical contraindications may prevent others from obtaining any or all of the procedures they desire.

Similarly, not all individuals who identify as transgender desire, seek, or obtain hormonal or surgical treatments for transition. To find authentic gender expression, some may choose to transition in some respects but not others. That is, the transition may just be *social,* wearing the clothing or accessories of their experienced gender, or it may entail taking gender-affirming hormones and/or undergoing surgery to acquire secondary sexual characteristics of their experienced gender. Some individuals who identify as transsexual object to being classified under the transgender umbrella, believing that those who experience a need to transition hormonally and/or surgically belong to a category distinct from those who do not. It is good clinical practice to ask patients which terms they use and how they wish to be addressed.

There is a great deal of popular confusion between being transgender and being homosexual. However, transgender identities, in and of themselves, do not necessarily reveal anything about one's sexual orientation. Whether one thinks of oneself as a man or woman does not predict whether they are attracted to men or to women. Additionally, the terms *homosexual* and *heterosexual* can lead to confusion when there are discrepancies between an individual's birth-assigned sex and experienced/expressed gender. Should the terms apply to an individual's pre- or post-transition identity? In such situations, sexual orientation may be better described, in conversations among professionals, as *androphilic* (attracted to men), *gynephilic* (attracted to women), bisexual, or *analophilic* (attracted to neither). For example, many transgender women who are sexually attracted to women might be described to professional colleagues as gynephilic or attracted to women; however, in conversations with patients, their preferred sexual orientation labels should be used.

The presence of marked incongruence between one's experienced/expressed gender and birth-assigned gender is listed among the criteria for the DSM-5 Text Revision (DSM-5-TR) diagnosis of *GD in adolescents and adults.* Importantly, *GD,* historically defined as unhappiness or a sense of inappropriateness with one's birth-assigned sex or the gender role associated with that sex, must cause clinically significant distress or impairment in order to satisfy the DSM diagnostic criteria of a disorder. There is also a DSM-5-TR diagnosis of *gender dysphoria in childhood* (GDC). Longitudinal studies have found that many individuals meeting criteria for GDC do not meet criteria for GD as adults. Instead, they may have a range of gender identities different from their sex assigned at birth but no longer meet criteria for GD (e.g., they may no longer meet the distress criterion or seek transition services), and others will identify as cisgender heterosexual adults, while many will identify as gay, "homosexual," or bisexual in adolescence or adulthood. However, most homosexual adults would not have met the criteria for GD as children. In the ICD-11, the gender diagnoses are *GI of adolescents* *and adults* and *GI of childhood.* To make these diagnoses does not require any distress or dysfunction criteria. For that and other reasons, the diagnoses were moved out of the Mental Disorders section of ICD into a new parent category: *conditions related to sexual health* (see this chapter's section on Diagnoses).

Transvestism refers to sexual urges and fantasies involving cross-dressing. When the behavior is distressing to a patient and brought to the attention of a psychiatrist, it may be diagnosed as *transvestic disorder,* which DSM-5-TR classifies as a *paraphilic disorder*. Cross-dressing is strongly linked in the popular imagination with homosexuality. However, in DSM-IV-TR, the diagnosis of *transvestic fetishism* could only be made in heterosexual men as most fetishistic cross-dressers are heterosexual men who cross-dress in private. These men are often married to women who may or may not know about their cross-dressing interests. DSM-5 removed the restriction to heterosexual men, opening the diagnosis to women or gay men who cross-dress out of erotic sexual interest. However, the diagnosis still requires that cross-dressing be a source of sexual arousal and that individuals experience significant distress or impairment because of their associated fantasies, urges, or behaviors. In any event, most gay men and lesbians do not cross-dress. However, there are social venues within gay and lesbian communities that allow for public cross-dressing. These may include either socially performative events (gay pride, Carnival, Halloween, or Mardi Gras parades) or cross-dressing as a form of paid entertainment (drag shows). Some, although not all, cross-dressers may identify as transgender individuals.

THEORIES

Scientific and social theorizing about gender diversity began in the middle of the 19th century. Although there are theories purporting to explain the origins of any gender identity, at present, it should be emphasized that the manner in which either transgender or cisgender identities develop is unknown.

History

19th and Early 20th Century Theories. The early history of theorizing about gender diversity was conflated with theories of what is today referred to as homosexuality. Many theorists routinely conflated homosexuality with transgender identities, relying upon binary beliefs that used conventional heterosexuality and cisgender identities as a frame of reference. For example, in the mid-19th century, German lawyer and activist Karl Ulrichs hypothesized that some men were born with a woman's spirit trapped in their bodies. He believed these men constituted a *third sex* and named them *urnings.* While historians of homosexuality unremarkably and routinely seem to regard Ulrichs' urnings as homosexual men, a female spirit in a male body closely resembles the narratives of 20th-century theories of transsexuality.

Until the early 21st century, with rare exceptions, transgender presentations were usually classified as "psychopathologic." One early exception was Carl Westphal's 1870 account of *Contrary Sexual Feeling,* the case of a young woman who cross-dressed as a boy and who was attracted to women with whom she formed relationships. Richard von Krafft-Ebing, on the other hand, reinforced the psychopathologic view in his landmark publication, *Psychopathia Sexualis,* an early psychiatric diagnostic manual. There he documented cases of individuals who desired to live as members of the other sex and those who had been born to one sex and were living as members of the other. In a chapter entitled "General Pathology," he presented what today would be thought of as transgender representations as cases of what he called *Metamorphosis Sexualis Paranoia.* In these examples, there was a significant conflation between homosexuality and transgender presentations.

German psychiatrist Magnus Hirschfeld is credited with being the first to distinguish the desires of homosexuality (to have partners of the same sex) from what he called *transvestism* (to live as the other sex). However, those distinctions were not broadly accepted until decades later. Hirschfeld also assisted surgeons in Europe who were already experimenting with GCS in the 1920s.

Mid-20th Century. The possibility of medical and surgical gender transition seized the popular imagination when American George Jorgensen went to Denmark as a birth-assigned male and returned to the United States in 1952 as transgender woman, Christine Jorgensen. In the wake of much public and professional controversy about Jorgensen's transition, Christian Hamburger and the other Danish physician who performed her surgery published a report of their treatment of her "transvestism" in the *Journal of the American Medical Association.* The publicity surrounding Jorgensen's transition eventually led to greater popular, medical, and psychiatric awareness of a then little-known concept that would eventually come to be known as *gender identity,* as well as recognition of an increasing number of people wishing to "crossover." For those who eventually would come to identify as transsexual and later transgender, increased public discussions of gender reassignment and gender identity would provide a way to put a name to their feelings and desires. As a result, an experience and presentation of gender once considered exceedingly rare gradually became more commonplace.

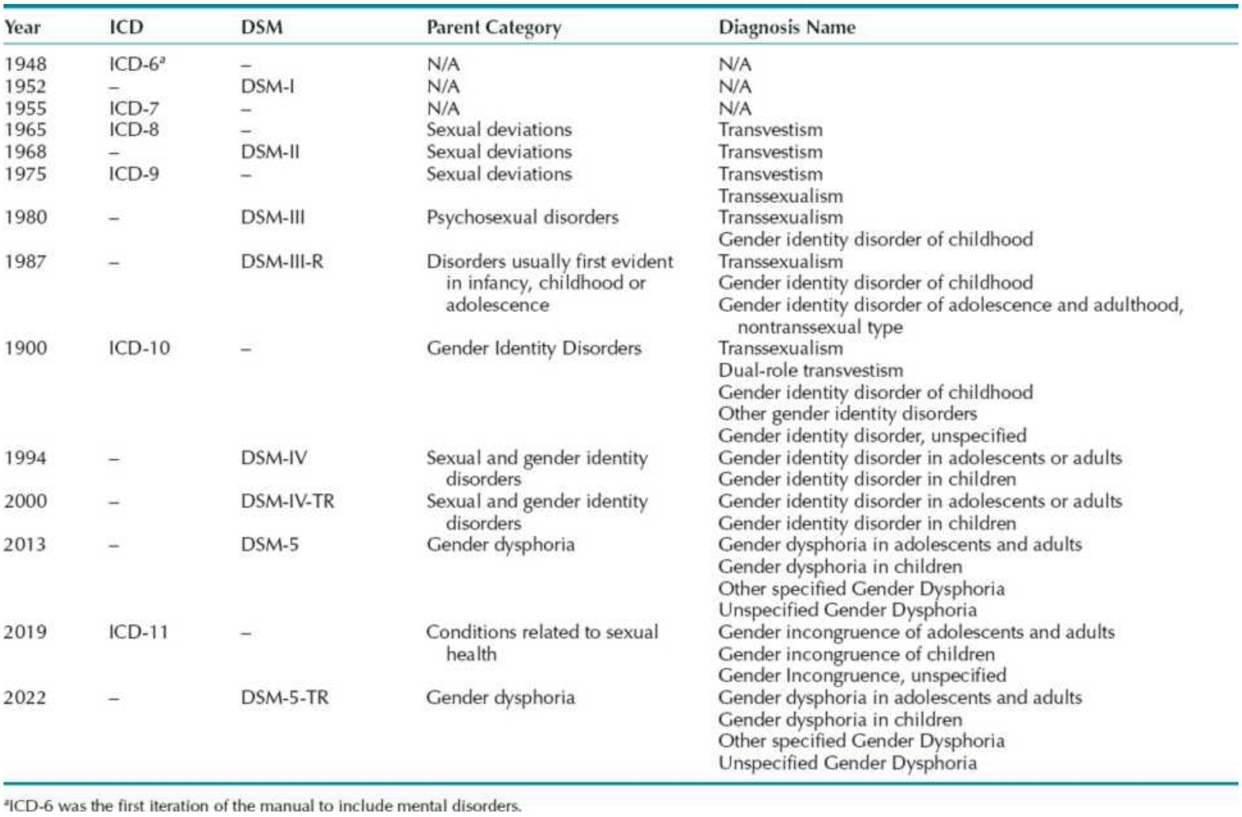
However, at the time of Jorgensen's 1950s transformation and for several decades thereafter, many professionals were critical of offering hormonal and surgical gender-affirming procedures. Many physicians and psychiatrists criticized using surgery and hormones to irreversibly—and in their view incorrectly—treat people suffering from what they perceived to be either a severe neurotic or psychotic, delusional condition in need of psychotherapy and "reality testing." It was in this cultural context that the first two editions of the DSM published in 1952 and 1968, respectively, did not include any gender diagnoses. The diagnosis of trans-sexualism (sic) first appeared in 1975 in the ICD-9. In 1980, a newly revamped DSM-III offered new diagnoses based on a growing body of research on child and adult gender identity. Table 21.4–1 outlines the placement of gender diagnoses in the ICD and DSM manuals.

The decisions to include *transsexualism* in the ICD and DSM were based on a growing body of research and clinical observations, most notably the work of John Money, Harry Benjamin, Robert Stoller, and Richard Green.

John Money, a psychologist and sexologist, first began publishing theories regarding gender identity development in the 1950s. Based on studies of children born with DSDs, he theorized that one's sense of being male or female—what eventually came to be known as one's gender identity—was acquired and that acquisition was primarily determined by external environmental factors. Citing cases of gender assignment in intersex children born with ambiguous genitalia, Money believed that parental attitudes and rearing practices had a strong effect on whether a child would accept the gender category to which it had been surgically assigned. Although Money believed that biology also played a role, he believed that the role of the psychosocial environment was critical and that any biologic predisposition could be overridden if parents unambiguously reinforced the gender assignment. Based on his observations, he suggested that a person's gender identity was fixed by 3 years of age and considered efforts to change a person's gender identity difficult if not impossible in anyone older. Pessimism about changing an adult's gender identity increased interest in an alternative for those dysphoric in their assigned gender: gender reassignment.

In the mid-1960s, in the wake of Money's theoretical work and his clinical and research findings, Johns Hopkins opened the first university-affiliated, multidisciplinary gender clinic offering gender reassignment to those seeking treatment. More than 40 academic centers in the United States would later open gender clinics as well. More recently, observations of gender identity outcomes in individuals with particular DSD syndromes have suggested that the influence of biologic factors on gender identity is stronger than that suggested by Money.

Table 21.4–1.
Gender Diagnoses in the ICD and DSM



Year	ICD	DSM	Parent Category	Diagnosis Name
1948	ICD-6[a]	–	N/A	N/A
1952	–	DSM-I	N/A	N/A
1955	ICD-7	–	N/A	N/A
1965	ICD-8	–	Sexual deviations	Transvestism
1968	–	DSM-II	Sexual deviations	Transvestism
1975	ICD-9	–	Sexual deviations	Transvestism Transsexualism
1980	–	DSM-III	Psychosexual disorders	Transsexualism Gender identity disorder of childhood
1987	–	DSM-III-R	Disorders usually first evident in infancy, childhood or adolescence	Transsexualism Gender identity disorder of childhood Gender identity disorder of adolescence and adulthood, nontranssexual type
1900	ICD-10	–	Gender Identity Disorders	Transsexualism Dual-role transvestism Gender identity disorder of childhood Other gender identity disorders Gender identity disorder, unspecified
1994	–	DSM-IV	Sexual and gender identity disorders	Gender identity disorder in adolescents or adults Gender identity disorder in children
2000	–	DSM-IV-TR	Sexual and gender identity disorders	Gender identity disorder in adolescents or adults Gender identity disorder in children
2013	–	DSM-5	Gender dysphoria	Gender dysphoria in adolescents and adults Gender dysphoria in children Other specified Gender Dysphoria Unspecified Gender Dysphoria
2019	ICD-11	–	Conditions related to sexual health	Gender incongruence of adolescents and adults Gender incongruence of children Gender Incongruence, unspecified
2022	–	DSM-5-TR	Gender dysphoria	Gender dysphoria in adolescents and adults Gender dysphoria in children Other specified Gender Dysphoria Unspecified Gender Dysphoria

[a] ICD-6 was the first iteration of the manual to include mental disorders.

Harry Benjamin, a physician, is credited with both popularizing the term *transsexual* and for raising awareness about trans individuals within the medical profession. Benjamin offered transgender individuals hormonal treatment at a time when mainstream psychiatry and medicine regarded gender-incongruent individuals as confused homosexuals, neurotics, transvestites, people with schizophrenia, or some combination thereof. Benjamin believed that transsexuality was a biologic disorder arising, for example, in birth-assigned males due to brain feminization in utero. Consistent with his essentialist view, he believed psychotherapeutic attempts to change a gender identity were futile. Among the first physicians to experiment with hormonal and surgical treatments for aging, he eventually pioneered the treatment of gender dysphoric individuals using sex hormones. Notably, he accomplished this in a private practice setting without either university or academic support. In acknowledgment of his early advocacy, in 1979, the newly formed Harry Benjamin International

Gender Dysphoria Association (HBIGDA) was named in his honor. HBIGDA, which later changed its name to World Professional Association for Transgender Health (WPATH), would go on to develop *Standards of Care (SOC)* for treating individuals with gender dysphoria. The WPATH SOC are periodically revised and, at the time of this writing, are presently in their eighth version (SOC v8).

Robert Stoller was an American psychiatrist and psychoanalyst whose theorizing, like Money's, grew out of clinical experience with both transsexual individuals and individuals with somatic intersex conditions. Stoller is credited with introducing the concept of *gender identity* into both the psychoanalytic and psychiatric literature. In contrast to Benjamin's essentialist views, Stoller believed that in some cases, childhood family dynamics were responsible for "causing" adult transsexualism. Stoller, influenced by the separation-individuation theories of Margaret Mahler, opined that GD in prepubescent boys was a developmental arrest due to an excessively close and gratifying mother–infant symbiosis that prevented the child from adequately separating himself from his mother's female body and feminine behavior.

Richard Green, who at different stages of his career trained with Money, Benjamin, and Stoller, most notably studied gender diversity in prepubescent children. His book, "*The Sissy Boy Syndrome" and the Development of Homosexuality,* was a prospective study that tracked into adulthood the development of 66 gender-atypical boys who stated a wish to be a girl. Seventy-five percent of the children Green studied grew up to be gay men. This finding was consistent with studies done over the years at specialized gender clinics where the majority of children, mostly assigned male at birth, grew up to be gay and not transgender. Green, who served on the DSM-III Subcommittee on Psychosexual Disorders, recommended including the diagnoses of *transsexualism* and *GID of childhood* in the 1980s DSM-III. The childhood diagnosis would subsequently make an appearance in 1990's ICD-10 as well.

Transgender Emergence. Following the publication of a 1979 John Hopkins study by Jon Meyer and Donna Reter citing "no objective improvement" in transsexual women who had received GAS, Hopkins closed its gender clinic. Importantly, the conclusion of "no objective improvement" was based on a comparison of an "adjustment score" before and after transition. This score was a composite of variables that seem of questionable relevance to the resolution of GD today, including legal and economic considerations as well as marriage or "gender-appropriate" cohabitation. The study did, however, conclude that GCS was subjectively satisfying to recipients. Nevertheless, following the publication of this study, all but 3 of the more than 40 university-affiliated U.S. gender programs closed. This dramatically changed the delivery of medical care for GD in the United States. Prior to the closing of these clinics, in the 1960s and 70s, gender reassignment performed at university-based gender clinics was usually conducted with the aim that the recipient blend into a male/female, heteronormative binary mainstream. In the absence of university protocols, those seeking treatment had what transgender activist and writer Dallas Denny calls an "open market" for the treatment of their GD, as those desiring surgical and hormonal transition services were no longer screened for the potential to blend into the heterosexual, cisgender mainstream. Further, transgender individuals began to seek each other out as they were no longer constrained by the privacy requirements of gender clinics that kept them from meeting each other. The mid-1980s saw the creation of support groups and conferences at which they would meet and exchange ideas and experiences. By the 1990s, transgender individuals began to produce scholarly literature of their own. Also, starting in the 1990s, many of the existing lesbian, gay, and bisexual (LGB) civil rights advocacy groups began a process of *transgender inclusion* in recognition of the similarities in types of prejudice and discrimination faced by the entire LGBT community. Today openly transgender individuals from all walks of life are increasingly in the public eye. In recent years, antidiscrimination protections and/or hate crime laws for gender identity and gender expression have been enacted at the statewide level in 22 U.S. states and Washington DC. In 2012, the American Psychiatric Association (APA) issued position statements in support of transgender access to care and opposing discrimination against transgender individuals. Over the past 20 years, outcome studies following surgical gender reassignment have focused on subjective variables such as relief of GD, subjective sense of well-being, and satisfaction with transition as opposed to regret. Such studies have found the process of gender reassignment to be effective in lessening suffering and increasing subjective satisfaction, with major regrets being rare.

The 2012 APA Task Force on GID reviewed the evidence on satisfaction versus regret following GAS. Taken together, the studies suggest that major regrets are rare. For example, a review of 79 follow-up studies conducted between 1961 and 1991, including more than 1,000 MTF and 400 FTM patients, found that major regrets such as reversion to the gender assigned at birth occurred in only 1% to 1.15% of patients. Identified correlates of regret included an inadequate diagnosis of major mental health comorbidity, misdiagnosis, absence of adequate preparation, and poor family support. In 2018, similar results were reported based on the Amsterdam Cohort of Gender Dysphoria Study (1972 to 2015). Specifically, the percentage of those who underwent gonadectomy within 5 years of starting gender-affirming hormones remained stable over time (74.7% for transgender women and 83.8% for transgender men), and only 0.6% of transgender women and 0.3% of transgender men who underwent gonadectomy experienced regret. More recently, there have been anecdotal reports of *detransitioning* by individuals who may have successfully transitioned earlier in life but who now, for a variety of reasons, have returned to living in their gender assigned at birth. A few recent qualitative studies of detransitioned individuals indicate many reasons for making this decision.

Recent decades have also seen growing public awareness and acceptance of gender-diverse minors, be they prepubescent children or adolescents. Where once the predominant psychiatric approach for prepubescent children was to dissuade them from their gender-atypical interests, alternative treatment approaches have evolved (discussed later in this chapter). There has also been an increase not only in families allowing their children to socially transition before puberty but in schools and school boards willing to accommodate those transitions.

Mental Disorder or Normal Gender Diversity? Following greater visibility and paralleling gay activist protests of the mid-20th century, an increasing number of transgender-identified individuals and their allies challenge the characterization of transgender and transsexual identities, as well as GD, as mental disorders. Just as the gay community once argued for removal from an earlier diagnostic nosology, the transgender community has adopted similar normalizing arguments to make a case for removal. These include adopting normalizing etiologic theories, such as the belief that one is born transgender; adopting a transhistorical approach that connects modern transgender identities to historical figures and cultures; using modern cross-cultural studies to show that antitransgender attitudes are culture bound; using statistics regarding prevalence to refute the notion that transgender expressions are rare; underscoring the difficult, if not impossible, task of changing a gender identity; and adopting normative language to replace medical terminology.

In response to these social changes, there was much public debate about the retention of gender diagnoses in the DSM-5, starting with the appointment of the DSM-5 Workgroup on Sexual and Gender Identity Disorders in 2008 up until the publication of DSM-5 in 2013. The decision to retain the diagnoses in DSM-5 was in part based upon the need to maintain access to care for individuals seeking medical and surgical treatment; however, the name was changed to GD, which is more descriptive and less stigmatizing. While the use of V-codes was suggested and considered, this solution was ultimately rejected as limiting access to care since third-party payers do not reimburse for V-codes.

Similar concerns about perpetuating the stigma of a mental disorder were raised as the World Health Organization (WHO) revised the ICD, with the ICD-11 approved by the WHO Assembly in 2019. The Working Group on the Classification of Sexual Disorders and Sexual Health (WGSDSH) was charged with reviewing and evaluating clinical and research data informing gender diagnoses. As

WHO is part of the United Nations, in addition to its medical mission, it also has a human rights mission. Consequently, many advocates, several countries, the Council of Europe Commissioner for Human Rights, and the European Parliament advocated strong positions that issues related to transgender identity should not be classified as mental disorders in the ICD-11.

While reducing stigmatization associated with mental disorders is important, the argument for removing a diagnostic category from the Mental Disorders section of the ICD simply because mental disorders are stigmatized was neither compelling nor persuasive. Psychiatric illnesses, like “social deviance,” often create conflicts between individuals and society. Consequently, both the psychiatrically ill and minority groups are subject to stigma. Stigmatization of individuals with psychiatric disorders is a social problem across cultures. WHO, health care policy makers, psychiatrists, and other mental health professionals are actively engaged in trying to reduce the stigma of mental disorders in order to increase access to care and to encourage people to avail themselves of mental health services. Further, mental disorders are health conditions which is why they are in the ICD. One unintended consequence of belaboring distinctions between medicine and psychiatry is the perpetuation of existing stigma and prejudices against the mentally ill.

Nevertheless, the combined stigmatization of being transgender and of having a mental disorder diagnosis created a doubly burdensome situation for this population that contributed adversely to their health status, as well as to their attainment of human rights. For example, transgender people are much more likely to be denied care in general medical or community-based settings, given the perception that they must be treated by psychiatric specialists, even for conditions that have nothing to do with being transgender. Further, there are unique circumstances in the case of this particular diagnosis that relate to the ability of a person to be viewed as competent to make certain legal decisions. Government agencies in many countries have demonstrated a lack of understanding of the need to extend recognition of a change in legal gender status on identity documents such as passports, birth certificates, and drivers’ licenses. Courts may demonstrate prejudice by ruling against transgender people in child custody decisions in cases where being diagnosed with a mental disorder is used by an ex-spouse to call their competence as parents into question.

It should be underscored that from a historical perspective, the classification of gender identity diagnoses as mental disorders was serendipitous. It appears to have been based more on prevailing social attitudes at the time than on available scientific evidence. For example, if the social narrative at that time had been that transsexuality was related to a “sex atypical prenatal hormone exposure of the brain” rather than being a “sexual deviation,” the result could very well have been that “transsexualism” would have been placed in the ICD-10 chapter on “endocrine, nutritional, and metabolic diseases.” In fact, the etiology of the condition was unknown when placement decisions were made in the past, and it remains unknown now. There are no scientifically based criteria to differentiate normal and pathologic gender identity, and the manner in which *any* gender identity develops remains unknown and a matter of theoretical speculation. The extant scientific database cannot empirically answer the question of whether this diagnosis is purely a “mental” phenomenon as opposed to a biologic one. A number of studies posit physiologic rather than “mental” causes of transgender identification. In addition, many of the treatments employed today (e.g., hormonal, surgical, voice therapy, depilation) could not be construed as conventional mental health treatments. That is, today’s approaches to GI involve a focus on the body and social role rather than changing the individual’s experienced gender. There is no reason to expect that this approach will change in the foreseeable future.

Historically, based on the conceptualization of GI as a mental disorder, as well as the need to distinguish it from other mental disorders, many countries required psychiatrists and other mental health professionals to act as *gatekeepers* to transition services for transgender people. In some countries, transgender people wishing to transition must prove to psychiatrists that they are the “right” kind of transgender and that they have been so for a sufficiently long period of time in order to qualify for services. This has created some controversy, as many individuals seeking transition do not meet criteria for a psychiatric diagnosis nor do they desire mental health treatment, and the gatekeeping function may be seen as an unnecessarily burdensome requirement. How the gatekeeping role is performed has contributed to considerable tension between mental health professionals and transgender advocacy groups. In particular, mental health professionals may be viewed as gatekeepers rather than professionals who have been placed in a gatekeeping role. Being viewed as gatekeepers by those seeking services can interfere with the positive contributions that psychiatrists and other mental health professionals can make to the transition process. It can also be disheartening to those mental health professionals who see themselves as advocates for the transgender community to find themselves labeled as gatekeepers. In addition to ensuring that patients understand the potential benefits, risks, and limitations of their desired gender-affirming treatments, counseling and therapeutic approaches can be very important in helping an individual prepare for and cope with the personal and social effects of transition. In this regard, the role of mental health professionals is not fundamentally different from their participation as a part of assessment and treatment for individuals undergoing other complex, life-changing medical treatments, such as organ transplantation.

Consequently, in addition to recommending a name change to GI, WHO’s Working Group on Sexual Disorders and Sexual Health recommended that the diagnoses be removed from the ICD-11’s section on mental and behavioral disorders. This recommendation was accepted, and the diagnosis was moved out of the Mental and Behavioral Disorders section into a new chapter called *Conditions Related to Sexual Health.* A recommendation from advocacy groups that the diagnoses be listed as Z-codes (similar to DSM’s V-codes) was rejected for similar reasons: third-party payers, including national health services, do not reimburse for the treatment of Z-codes.

The retention of an ICD diagnosis for adolescents and adults has not been as controversial an issue as the retention of a diagnosis for prepubescent children. Even removing the diagnosis from ICD’s

Mental and Behavioral Disorders section has not satisfied some advocacy groups who argue that gender-diverse children are being stigmatized with a *medical diagnosis* where previously they complained of the stigma of a *psychiatric diagnosis.* These arguments have not been persuasive. Further, children with GI require access to care that is often complex and involves treatment of the family and social environment, as well as the child. Consequently, the ICD-11 diagnosis of GI in childhood narrowly defines the category so that gender-atypical presentations, in and of themselves, are not considered diagnosable conditions.

FREQUENCY

The prevalence of GD specifically, or transgender and gender-diverse identities in general, is hard to determine exactly for a variety of reasons, including concealment of these identities due to stigma as well as methodologic problems in defining the populations of interest and designing adequate sampling strategies. Researchers who study incidence and prevalence have tended to focus on individuals who presented to specialized gender clinics and received a diagnosis of GD or an earlier DSM or ICD equivalent. Most such prevalence studies have been conducted in European countries, and the prevalence for any GD diagnosis across populations has been assessed to be 0.0007% to 0.04% for those assigned male at birth and 0.007% to 0.02% for those assigned female at birth. Since not all who seek hormonal and surgical reassignment attend specialty clinics, the above rates are likely underestimates of transsexual individuals and clearly underestimates of transgender individuals who either do not desire or do not seek transition services. Studies that employ more inclusive sampling methods not restricted to specialty clinics tend to yield higher prevalence figures. Recent prevalence estimates based on surveys of self-reporting general population samples in the United States and Europe reveal much higher numbers. Responses vary, depending on how the question is asked. For example, self-identification as transgender ranges from 0.1% to 0.6 %, experiencing oneself as having an incongruent gender identity range from 0.6% to 1.1 %; feeling one is a person of different sex ranges from 0.4% to 0.6%; and the desire to undergo medical treatment ranges from 0.2% to 0.6 %.

In nonreferred children and adolescents, prevalence is believed to be less than 1%. In children, sex ratios of individuals assigned male at birth to individuals assigned female at birth range from 1.25:1 to 4.3:1. Recent studies show increasing numbers of children and adolescents presenting to specialty clinics, presentation at younger ages, more frequent early social transition, and a shift in sex ratio with a greater number of individuals assigned female at birth in adolescents and young adults.

DIAGNOSIS

DSM-5 Text Revision (DSM-5-TR)

The DSM-5 revision involved a diagnostic name change from GID and the creation of a new overarching parent category known as GD. One rationale for this change was to remove the stigmatizing term “disorder” from the diagnostic label. The term “dysphoria” also captures the aversive emotional component of the clinical presentation, as well as shifting clinical focus from “identity” per se to patient distress.

In addition, GD was moved out of an earlier parent category of sexual and gender identity disorders (where it was clustered with paraphilias and sexual dysfunctions) and into a separate category of its own. Other DSM-5 revisions included a new specifier, “with a disorder of sex development (DSD),” for individuals who have intersex conditions and develop symptoms of GD. This is in contrast to previous iterations of the DSM, where the presence of a somatic intersex condition was considered an exclusionary criterion for making a GID diagnosis. Any issues regarding the particular DSD condition and/or need for engagement in ongoing medical care should be clarified and appropriately addressed. The DSM-5 also included a new “post-transition” specifier for older adolescents and adults who have transitioned to full-time living in the desired gender.

Unlike the DSM-III and IV, DSM-5 removed the sexual orientation specifier as it no longer had any clinical relevance in the treatment of GD. The diagnostic criteria are unchanged in the DSM-5-TR.

The DSM-5-TR includes four GD diagnoses: GD in adolescents and adults, GD in childhood, other specified GD, and unspecified GD. The first two are described in greater detail later in this chapter.

Gender Dysphoria in Children. The diagnosis can only be made in children who meet two criteria, A and B, in the DSM-5-TR. Eight potential manifestations of criterion A are listed, of which at least six must be met. One of these six criteria must be “a strong desire to be of the other gender or an insistence that he or she is the other gender (or some alternative gender [that is neither conventionally male nor female] different from one’s assigned gender).” The other A-symptom criteria include preferring cross-dressing and rejecting conventional attire of one’s assigned gender; preferring gender roles of the other gender in make-believe play; preferring toys, games, or activities stereotypically associated with the other gender; and preferring play with children of the other gender. As children, those assigned male at birth typically reject masculine toys, games, and activities and avoid rough-and-tumble play; those assigned female typically reject feminine toys, games, and activities. These children frequently express a dislike of their sexual anatomy and may express the desire for the sex characteristics, primary and/or secondary, of the experienced gender. In addition to meeting six A criteria, Criterion B must be met, which requires the presence of clinically significant distress or impairment in social, school, or other important areas of functioning. While the presence of a DSD was an exclusionary criterion for diagnosing GID in previous editions of DSM, the DSM-5 added a new specifier: “with a DSD.” When this specifier is used, both the specific DSD, as well as the GD diagnosis should be coded. As some DSDs require ongoing medical care (e.g., salt-wasting congenital adrenal hyperplasia and individuals rendered agonadal by treatment), appropriate medical referrals should be offered, if there are any questions about the particular DSD diagnosis, as well as engagement in necessary medical care.

The differential diagnosis of GD in childhood includes simple atypical gender behavior in the absence of clinically significant distress or impairment. The diagnosis is not meant to merely describe nonconformity to stereotypical gender role and behavior such as “tomboyism” in girls or “girly” or “sissy” behavior in boys. The majority of such children are comfortable with their bodies and assigned genders and remain so in adolescence or adulthood. GD must also be distinguished from gender concerns that may arise as epiphenomena of coexisting disorders, including autism spectrum disorders (ASDs), personality disorders, or psychotic disorders, as well as a stated desire to be the other gender due to some perceived social advantage of being that gender or to escape a perceived disadvantage of the assigned gender (e.g., following sexual trauma). In cases where a child experiences GD during periods when psychotic symptoms are in remission, a psychotic disorder and GD may both be diagnosed. GD in childhood has different criteria sets than GD in adolescents and adults, and most children with GD in childhood do not subsequently meet diagnostic criteria for GD in adolescence and adulthood.

Gender Dysphoria in Adolescents and Adults. The DSM-5-TR diagnosis of GD in adolescents and adults is unchanged from the DSM-5. To establish the diagnosis, at least two of any of the six are required to be present for at least 6 months. These include a pronounced *incongruence* between one’s experienced or expressed gender and the primary/secondary sex characteristics of the *assigned* or *natal gender.* For prepubescent adolescents or those in puberty’s early stages, this symptom is expressed as aversive anxiety to *anticipated* secondary sex characteristics. Another criterion is a strong desire to be rid of the birth-assigned gender’s primary and/or secondary sex characteristics due to incongruence with one’s experienced/expressed gender as opposed to other motives. For prepubescent adolescents or those in puberty’s early stages, there is a strong desire to prevent further development of anticipated secondary sex characteristics. A third criterion is a strong desire for primary and/or secondary sex characteristics of the other gender. A fourth is a strong desire to be either of the other gender or some alternative gender, neither conventionally male nor female, rather than one's assigned gender. A fifth is a strong desire to be treated by others as a member of the other gender or some alternative gender. The sixth and final criterion is a strong conviction that one's feelings and reactions are more typical of the other gender or some alternative gender to the assigned gender.

There is also a B criterion of clinically significant distress or impairment in function in social, occupational, or other areas. As in the child diagnosis, there is a specifier, "with a DSD," that requires coding a specific DSD condition, if present, in addition to the GD diagnosis. As with the child diagnosis, any issues regarding the particular DSD condition and/or need for engagement in ongoing medical care should be clarified and appropriately addressed. There is also a "post-transition" specifier for individuals who have transitioned to living full time in the desired gender, regardless of a legal name change, who have undergone or plan to have at least one cross-sex medical or surgical procedure. This specifier allows individuals to maintain the diagnosis needed to access ongoing gender-affirming care (e.g., gender-affirming hormones), even if they no longer meet either the A or B criteria for the diagnosis after the transition.

The differential diagnosis of GD in adolescents and adults includes nondiagnosable *atypical gender behavior; transvestic disorder* (a paraphilia in which individuals are sexually aroused by cross-dressing—some individuals may meet criteria for both transvestic disorder and GD); *body dysmorphic disorder* (involving a wish to alter or remove a specific body part perceived to be unattractive or abnormally formed); and *schizophrenia* and *other psychotic disorders* (in which delusions of being another gender may present). Importantly, if the full criteria for GD are met in an individual with a psychotic disorder when the psychosis is in remission, the diagnosis of GD can still be made, as is the case if the GD preceded the onset of the psychotic illness. Some individuals assigned male at birth may seek castration to ameliorate psychological or physical effects of androgens yet still may identify as male or employ a different gender identity label such as male *eunuch*, *agender,* or *nonbinary*.

The DSM-5-TR contains two additional gender diagnoses. The first is *other specified GD*. This diagnosis is given when the patient has manifestations characteristic of GD, and the clinician wishes to specify why the full diagnostic criteria are not met. This typically occurs when a sufficient number of the A criteria are met, but the duration criterion is not met at the time the diagnosis is given. The second is *unspecified GD*. This diagnosis may be used when the clinician chooses not to specify why the full criteria are not met and may be appropriate, for example, when the clinician has spent insufficient time with the patient to clarify whether sufficient symptoms are present to meet diagnostic criteria.

ICD-11

The WHO's ICD gender diagnoses differ from those of DSM-5-TR in several ways. First, GID of childhood was renamed *GI of children,* while transsexualism was renamed *GI of adolescents and adults.* Second, both diagnoses were removed from the Mental and Behavioral Disorders section of ICD and are part of a new section entitled Conditions Related to Sexual Health.

Gender Incongruence of Childhood. ICD-11's GI of Childhood is characterized by a marked incongruence between an individual's experienced/expressed gender and the assigned sex in prepubertal children. A marked incongruence between the child's experienced/expressed gender and the child's assigned sex must be manifested by the following three indicators: (1) a strong desire on the child's part to be a different gender than the assigned sex or insistence that they are a gender different from one's assigned gender; (2) a strong dislike on the child's part of their sexual anatomy or anticipated secondary sex characteristics and/or a strong desire for the primary and/or anticipated secondary sex characteristics that match the experienced gender; and (3) make-believe or fantasy play, toys, games, or activities and playmates that are typical of their experience rather than their assigned sex. In addition, the incongruence must have persisted for about 2 years, so the diagnosis cannot be made before approximately age 5. The diagnosis can only be assigned to children before puberty.

Gender Incongruence of Adolescence and Adulthood. GI of adolescence and adulthood (GIAA) is characterized by a marked and persistent incongruence between an individual's experienced gender and the assigned sex. The diagnosis cannot be assigned prior to the onset of puberty. GIAA often leads to a desire to transition in order to live and be accepted as a person of the experienced gender. Establishing congruence may include hormonal treatment, surgery, or other health care services to make the individual's body align, as much as desired and to the extent possible, with the experienced gender.

Diagnostic guidelines include a marked incongruence between the individual's experienced gender and the assigned sex, as manifested by at least two of the following four criteria: (1) a strong dislike or discomfort with one's primary and/or secondary sex characteristics (in adolescents, anticipated secondary sex characteristics) due to their incongruity with the experienced gender; (2) a strong desire to be rid of some of all of one's primary and/or secondary sex characteristics (in adolescents, anticipated secondary sex characteristics) due to their incongruity with the experienced gender; (3) a strong desire to have the primary or secondary sex characteristics of the experienced gender; and (4) a desire to be treated (to live and be accepted) as a person of the experienced gender. The diagnosis cannot be assigned prior to the onset of puberty, and the GI must have been continuously present for at least several months.

Reconciling DSM-5-TR and ICD-11 Diagnostic Codes

While the DSM has its own coding system, which at one time was accepted by most insurers, in 2015, the United States began requiring the use of ICD-10 codes for insurance reimbursement. Consequently, DSM-5-TR also includes equivalent ICD-10 codes for all its diagnostic categories. The DSM-5-TR diagnosis of GD in adolescents and adults (302.85) also lists the ICD-10 diagnosis code for transsexualism (F64.0) as an equivalent code.

However, the diagnostic codes of ICD-11 are not equivalent to those of ICD-10. The code for ICD-11's GIAA is HA60. This means that although GIAA is no longer categorized as a mental disorder in ICD-11, the United States is still using an ICD-10 code that continues to code the condition as a mental disorder (F codes). As it took 25 years for the United States to adopt ICD-10, which was first approved by WHO in 1990, it is not clear when ICD-11 codes will be adopted in the United States. At the time of this writing, the APA is exploring ways to integrate the ICD-11 changes into the U.S. coding system (ICD-10 Clinical Modification or ICD-10-CM). However, given the bureaucratic obstacles involved in making such changes, the adoption of ICD-11's nonpsychopathologizing code is not imminent.

ORIGINS OF GENDER DYSPHORIA

Because GI does not necessarily lead to clinically significant distress, understanding its etiology requires understanding both the acquisition of gender identity and how a mismatch between assigned and experienced gender lead to clinically significant distress in some individuals. This section examines theories about the acquisition of gender identity, both congruent and incongruent with the sex assigned at birth, and then about the origins of distress resulting from GI in different age groups.

Acquisition of Gender Identity

Studies focusing separately on biologic and psychosocial factors suggest that both contribute to gender identity, but the precise role of each, their interactions, and the contribution of the individual to the process remain incompletely understood. Early interest in gender identity focused on the infant/toddler's cognitive abilities during the period of gender identity formation and elucidating the limits of the developmental window of this period. The studies of John Money and his collaborators briefly discussed previously in this chapter suggested a period of maximal sensitivity for the acquisition of gender identity that ends at approximately age 2. They found that among children who experienced gender reassignment (usually in the context of a DSD or penile injury) after the neonatal period, 11 of 14 adjusted to the reassignment without complications if the reassignment occurred prior to 27 months of age compared to only 1 of 4 who adjusted to the reassignment if it occurred after 27 months. Subsequent work of Money and others suggested that gender identity may be influenced beyond this period but that after some imprecisely defined time, it becomes more or less impervious to change. In other words, they concluded that gender identity is determined primarily by rearing practices during the first 2 years or so after birth.

Subsequent research by others concluded that infants begin to categorize gender-relevant attributes prior to the development of expressive language. For example, at 9 months, infants can associate male and female faces with male and female voices, respectively, looking longer at a female than a male face when a female voice was presented and vice versa. By 18 months, infants associate gender labels such as “lady” or “man” with female and male faces. As language develops, by 15 to 24 months, toddlers can label adults as male or female and, by 30 months, can label peers and self appropriately by gender. As gender labels emerge, in the majority of individuals, a preference for play with peers of the same gender emerges, and boys and girls tend to ascribe more positive attributes to their own gender and more negative attributes to the other. Some toddlers, however, show a preference for peers of the other gender and may even label themselves as the other gender as early as between the ages of 2 and 3.

By age 2, children can recognize their own genitals when shown anatomically correct dolls. Although by age 3 they may be aware that boys have penises and girls do not, less than half were found to understand this anatomic difference as the basis for gender categorization even by age 5. Between the age of 4 and 6, many children have yet to master the concept of *gender constancy,* an understanding that external changes in appearance or activity do not change one’s sex/gender (in the context of these studies, sex and gender are used interchangeably). Thus, they show confusion when asked whether a change in behavior or clothing (such as a boy playing with a doll and wearing a dress) would change their sex/gender. Similarly, they may have yet to master the concept of *gender stability,* the understanding that for most individuals, sex/gender remains constant throughout life. It is not until age 6 or 7 that nearly all children understand that genitals are the primary basis for sex/gender categorization and that sex/gender for most people is constant and stable. These cognitive limitations leave open the possibility of a world for young children in which the feeling that one is a sex/gender other than that assigned at birth would not be immediately countered by the awareness that, for most people, one's sex/gender assigned at birth is retained for life. For example, until the age of 6 or 7, a child assigned female at birth who does not understand the association between external genitalia and sex/gender has not mastered the concept of gender constancy and may believe that she could grow up to be a man merely by dressing and acting like a man.

Role of Psychosocial and Biologic Factors. The permissive, direct, and indirect/interactional models for conceptualizing the potential roles of biologic and psychosocial factors outlined for the development of sexual orientation may apply to gender identity as well.

MODEL OF PERMISSIVE BIOLOGIC EFFECTS. In this model, biology plays a permissive role by providing the neural machinery through which gender identity is inscribed by formative experience. A permissive role could also include delimiting the developmental stage during which the relevant formative experiences must occur. For example, some songbirds must learn their species' song by hearing it during a restricted period of early development. While the song is clearly acquired through experience, biology determines the sensitive period during which that experience must occur. Once a particular song has been acquired, that will be the bird's song for life; it will not be able to unlearn that song or to acquire another. This is not meant to imply that gender identity might be acquired by simple mimicry. Instead, it shows that phenomena acquired through experience may, nonetheless, be immutable.

MODEL OF DIRECT BIOLOGIC EFFECTS. In this model, the actions of biologic factors such as genes or hormones would directly influence the organization or activity of brain circuits that mediate gender identity. The brain is viewed as possessing an intrinsic (i.e., constitutional) gender identity or predisposition, the expression of which could nonetheless be subsequently modified by experience.

MODEL OF INDIRECT BIOLOGIC EFFECTS. This model addresses the contribution of individual differences, some of which may be constitutionally influenced. In this model, biologic factors influence gender identity only indirectly as the more direct or immediate action of biologic factors is upon temperament or other personality traits. From birth, these personality or temperamental traits influence how an individual experiences, interacts with, and modifies the environment. This would include how an individual participates in shaping the relationships and experiences thought by some to influence the development of gender identity. Although similar to the model of permissive biologic effects, the model of indirect biologic effects goes further and suggests that the relevant formative experiences may, themselves, be strongly affected by biologically influenced personality variables.

An impact of psychosocial factors in the acquisition of gender identity has been documented in a large body of research in developmental psychology on normative development. These factors include verbal labeling (e.g., as a boy or girl) and nonverbal gender cueing (e.g., mannerisms, clothing, hair length, and style) of children by parents and others in their social environment, the shaping of gendered behavior by positive and negative reinforcement and later by explicit statements of gender-role expectations. Problems in parent–child attachment interacting with temperamental dispositions in the child have been suggested to be causally implicated in GD and have been cited as a focus for psychodynamic therapy of the child. Child psychologist, Susan Coates, observed higher levels of psychopathology in clinical samples of primary caregivers and suggested that parental psychological abnormalities may contribute to GD. For example, a child assigned male at birth with a clinically depressed mother may identify with her in an attempt to elevate her mood. These observations, however, do not distinguish between cause and effect.

A review of the clinical data on individuals with somatic intersex conditions (aka DSDs) suggests that some individuals with functional androgen receptors and prenatal exposure to male-typical levels of androgens appear to have the capacity at birth to develop either a male or female gender identity depending on the gender of rearing. When assigned female, these individuals nevertheless have an increased likelihood of exhibiting masculinized play preferences and GD, with some ultimately rejecting the female identity and role. The proportion that ultimately rejects the female assignment is unknown because this can occur quite late in life, varies across DSD syndromes, and relatively few studies have followed and adequately assessed affected individuals in adulthood. The probability of switching to a male gender identity and role is perhaps highest in androgen-sensitive individuals whose testes are left in place until puberty. These data are open to a variety of interpretations, including the one that androgens act by modifying hypothetical brain circuits that mediate gender identity (direct model) or that androgens bias behavioral or temperamental propensities in a manner that facilitates the acquisition of a male identity (indirect model). In addition to acting prenatally, the elevated androgen secretion that occurs in the neonatal period and again at puberty might reinforce the effects of prenatal androgens. At puberty, the psychological impact of somatic virilization in response to elevated androgens must be considered in addition to the possibility of physiologic effects on the brain. Since the mid-1950s, the majority of XY individuals with somatic intersex conditions and markedly incomplete masculinization of the external genitalia have been assigned female. Thus, there are inadequate data upon which to base speculations about gender development in individuals with low prenatal androgen exposure who were assigned male.

A hypothesis that appears to be growing in popularity is that cross-gender identification results from a brain-limited form of intersexuality, that is, in transgender individuals, some brain regions or circuits that are involved in gender identity differ between cisgender men and women and are sexually discordant with the rest of the body in transgender individuals. This hypothesis is derivative of Ulrichs' 19th-century notion of a spirit of one sex trapped in the body of the other sex. Consistent with this hypothesis, based on their work with postmortem material, Dick Swaab and collaborators in the Netherlands have reported that a subcomponent of a brain structure called the bed nucleus of the terminalis varies in size as a function of gender identity rather than sex assigned at birth, a study that has yet to be replicated. Additional studies have described other brain differences, both anatomical and neurophysiologic, but the evidence at this point is insufficient for categorizing transgender people as having a form of CNS-limited intersex condition. Similarly, the literature on concordance for GD in monozygotic and dizygotic twins lends some support for a role of genetic factors, especially in individuals assigned male at birth. Due to small sample sizes and the absence of genotype studies, however, definitive conclusions cannot be drawn.

Controversial Issues

AUTOGYNEPHILIA IN BIRTH-ASSIGNED MALES. Psychologist and sex researcher Ray Blanchard has hypothesized two major developmental pathways leading to GD in transgender adults. In this theory, "homosexual transsexuals" are effeminate, gender-atypical birth-assigned boys who are attracted to partners of their own birth-assigned gender. That is to say, they are *androphilic* or attracted to men. The other group consists of what he terms "heterosexual transsexuals" who are *gynephilic* (attracted to women) and who are usually not overtly gender atypical as children and who often spend much of their lives in relationships with women. The latter group often has a history of cross-dressing in secret that first starts out as a means of sexual arousal and may go on to develop *autogynephilia,* in which a birth-assigned male finds the fantasy of being a woman to be sexually arousing. Although also attracted to women, these individuals are often aroused at the fantasy of having sex or actually engaging in sex with men who treat them as women. Cross-dressing, arousal to cross-dressing, or fantasies of being female are not classified as psychiatric disorders unless they cause clinically significant distress or impairment in important areas of functioning. In some cases, individuals with autogynephilia later develop GD and seek gender reassignment. After transition, they may prefer to engage in relationships with cisgender or transgender women.

Although the theory of an autogynephilic pathway to transsexualism has been in the research literature for decades, in recent years, it evoked controversy. While some members of the transgender community do identify as autogynephilic, others find offensive the linkage of transgender identity with paraphilia as well as the linkage of the desire to transition gender to sexual arousal. Some see it as reductionistic to hypothesize only two pathways to an identity that, in clinical practice, appears to be quite heterogeneous in its development. One scholarly critic of the concept is Charles Moser, a sexual medicine expert, who surveyed 29 birth-assigned women and found 93% of them met Blanchard’s criteria for autogynephilia. This finding is at odds with Blanchard’s theory that the condition does not occur in birth-assigned women and is a type of “male sexuality.” Moser argues that the meaning of a sexual interest in one’s own body is not well understood for either cisgender or transgender individuals of either sex assigned at birth. Transgender activist and biologist Julia Serano further notes that a correlation between autogynephilia and GD does not imply causation. She notes (1) that there are exceptions to the two subtype taxonomy (e.g., large numbers of androphilic MTF individuals who experience arousal by presenting female); (2) that some transgender people experience such arousal as a passing phase rather than a pressing paraphilic sexual drive leading to GD; and (3) that many nonandrophilic MTF transsexual individuals experienced the desire to be the other gender long before they experienced arousal to presenting as women or fantasizing of doing so.

RAPID-ONSET GENDER DYSPHORIA. In 2018, Lisa Littman published a study of 256 parental reports that their adolescent children who were assigned female at birth reported an onset of GD either during puberty or after its completion. The GD was reported to occur in the context of belonging to a peer group where one, multiple, or even all of the child's friends reported being gender dysphoric or transgender identified at the same time. Parents also reported their children demonstrated increased immersion in social media use prior to disclosing a transgender identity. The study defined "rapid-onset gender dysphoria" (ROGD) as GD beginning in adolescence or young adulthood in individuals who would not have met the criteria for GD in childhood. The study claimed these findings were inconsistent with existing research literature about the onset of GD/GI. It also raised questions of whether GD of this type, as with eating disorders in adolescents, could be a product of social contagion.

The study's publication provoked immediate criticism and controversy, leading the journal to request a postpublication review. Activists saw the study's publication as an effort to discredit the authenticity of transgender identities. A methodologic criticism was the study's selection bias in interviewing parents rather than the children or the clinicians evaluating the children. Further, the onset of GD without any features of GD before childhood is not a novel finding since prepubescent children with GD have long been viewed as a separate patient group from those who have GD onset in adolescence or adulthood. The study was republished in 2019 with some minor changes and caveats, emphasizing that ROGD was not a formal diagnosis and addressing the study's limitations as well as its potential utility in hypothesis building.

Origins of Distress Associated with Gender Incongruence

An objection to retaining GD as a psychiatric diagnosis in DSM is that it identifies gender-diverse identities and expression as pathologic when the distress required for the diagnosis may be related to the reaction of the social environment to the child's gender diversity. Since not all who experience a mismatch between their assigned and experienced gender experience clinically significant distress, the origins of distress should be considered separately from the origins of the cross-gender identification. Psychologist, Diane Ehrensaft, suggests that in most children with GD, the distress arises from stigma and prohibitions within the child’s social environment. She bases this suggestion on her observation that distress often resolves or diminishes when gender dysphoric children are allowed to freely express their experienced gender. Another hypothesis, for which there is very limited support, is that for some individuals, the transgender identification might, itself, be an expression of distress due to inadequate parenting or loss of a parent. For example, a boy who loses his mother through death or emotional withdrawal may suddenly show a preference for stereotypically feminine attire and state that he is or wants to be a girl. Some have interpreted such cases as the boy replacing the lost mother through identification and imitation. The ICD diagnosis of GI bypasses this controversy altogether as it requires no distress criterion to make a diagnosis.

Parents may act to limit social stigma and prohibitions in preschool-aged children in the home; however, unless preventive measures are taken, starting school and increasing interactions with the outside world may prove traumatic and exacerbate dysphoria. For some, the onset of puberty has been associated with the resolution of GD, with some reporting that pubertal changes forced them to accept that they were not the gender they had experienced themselves to be. For others, the onset of puberty and development of the secondary sex characteristics of the gender assigned at birth exacerbate dysphoria and may precipitate an emotional crisis. The foregoing pertains to those in whom GD began in childhood and persisted into adolescence. The origins of GD with onset in later adolescence or adulthood are more poorly understood, especially when there was no history of gender nonconformity observed in childhood. In some individuals, as mentioned previously in this chapter, late-onset GD has been hypothesized to be erotically driven (*autogynephilia*) and may entail a history of arousal to cross-dressing prior to the onset of anatomical dysphoria. Alternatively, the authors of a study of military veterans with late-onset GD suggested that the apparent late onset was due to other psychological factors. Specifically, many transgender veterans who were assigned male at birth reported that they joined the military in an attempt to purge their transgender feelings (*suppression*), believing that the military environment would make men of them, while others arrived at this interpretation after the fact (*repression*).

Directions for Future Research

Extensive research is needed on GD, especially with respect to identifying, understanding, and addressing the needs of individuals with GD in a manner that avoids stigma. This is particularly important in light of the considerable body of evidence linking stigma and *gender minority stress* to pronounced mental and physical health disparities seen in the transgender population. *Gender minority stress* refers to the high levels of chronic stress experienced by transgender people. Stressors include ridicule and bullying on the basis of gender nonconformity, intentional misgendering, exclusion from gendered spaces consistent with one's gender identity or gender presentation, as well as discrimination in multiple arenas, including employment, housing, and even health care. Much of the research linking minority stress to health disparities has been conducted in the arena of public health. Mental health disparities linked to minority stress in transgender populations include elevated rates of depression, suicidality, post-traumatic stress disorder, and substance abuse. In addition, many transgender individuals report avoiding health care due to past experiences of stigma and/or anticipation of stigma, and this avoidance exacerbates health disparities. Thus, transgender populations also exhibit marked general health disparities.

Considerable literature on GD addresses the identification of predictors of desistence versus persistence of GD in youth but, to date, no such reliable predictive system has been found. Recommendations for the minimization of stigma and its adverse impacts on self-esteem should be prioritized. This will entail considering the home and social environments in developing interventions aimed at minimizing stigma and optimizing long-term outcomes. Research is also needed on the selection of adolescents for pubertal suppression as well as the short- and long-term benefits and risk profiles of the treatment with respect to social, health, and psychological endpoints. The same holds true regarding greater individualization for the timing of the initiation of gender-affirming hormones. The range of needs of individuals with both GD and a DSD also requires greater attention.

There is also considerable interest in identifying genetic, endocrine, and brain correlates of GD. Studies of the development of gender identity in individuals with some DSDs have yielded some insights into hormonal pathways that may affect gender identity in individuals with DSDs; however, their relevance to GD in the absence of a DSD precludes broad generalizations.

There has been considerable speculation that the hormonal exposure of the developing brain, whether due to gene-controlled mechanisms (e.g., hormone production, hormone receptor mechanisms) within the fetus or exogenous factors (e.g., hormonal exposure or stress to the mother during pregnancy), may strongly influence or determine gender identity. In other words, GD could represent a brain-limited intersex condition. While there is some support for such hypotheses, definitive data are currently lacking. For example, the structure of some brain regions has been reported to vary between cisgender men and cisgender women and to be sex reversed in transgender individuals; however, such studies lack consistent replication. In addition, other sexually dimorphic attributes of the brain have been reported to shift on receipt of gender-affirming hormones. Again, however, replication is insufficient to date to allow strong conclusions.

Clinical research is much needed to better understand the substrates of the distress and impairment that are required for the diagnosis of GD. In particular, is distress intrinsic to one’s gender identification and expression, per se, in response to a perceived discrepancy between one’s sense of self and their body or sex assigned at birth, or in response to the disapproving reactions of others to the perception of one’s gender atypicality?

Research is also needed to better inform clinically appropriate interventions and their optimal timing and contexts, for example, addressing GD in the context of entering school, subsequent decisions about pubertal suppression and starting gender-affirming hormones, as well as decisions about whether to transition gender at school and, if so, exactly how and when.

The origins of gender identity are of broad general and theoretical interest, while the causes of the distress and impairment in GD demand research because of their implications for clinical interventions. Due to the low prevalence of GD and the heterogeneity of presentations, the research could be facilitated best if clinics pool their population samples and employ standardized assessments and interventions. Longitudinal studies from childhood through adulthood of such pooled samples have the potential to not only inform best clinical practices but to identify the range of factors that influence gender identity and its stability or change across development.

SOCIAL AND CULTURAL ISSUES

Delineating the full extent of social and cultural issues affecting transgender individuals is beyond the scope of this chapter. Among the *stigmatizing* challenges some transgender individuals face are rejection by family (leading to homelessness for some adolescents), estrangement from children produced in pretransition heterosexual relationships, rejection by peers, rejection by religious authorities, lack of acceptance from school authorities, bullying, harassment, job discrimination, lack of adequate and affirming medical and mental health care, and being subjected to violence. Members of the transgender community have produced or contributed to a sizable literature detailing personal stories of coming out as transgender that continues to grow. These include Jennifer Finney Boylan's *She's Not There: A Life in Two Genders,* Jamison Green's *Becoming a Visible Man,* and the multiauthored volume, *Trans Bodies, Trans Selves,* edited by Laura Erickson-Schroth.

CLINICAL APPROACHES

The most widely recognized guidance for treating persons with GD comes from the World Professional Association for Transgender

Health Standards of Care (WPATH SOC), now in their eighth revision. The SOC v8, which uses the ICD-11 diagnosis of Gender Incongruence (GI) endorse psychological evaluation and a flexible staged transition in which fully reversible steps (e.g., presenting as one's experienced gender or social transition) usually precede partially reversible steps (hormonal treatments to suppress development of unwanted secondary sex characteristics or to bring about the secondary sex characteristics consistent with one's experienced gender), which precede irreversible surgical procedures (e.g., gonadectomy, vaginoplasty in individuals assigned male at births, hysterectomy, salpingo-oophorectomy and phalloplasty in individuals assigned female at birth). Mastectomy and male breast construction in individuals assigned female at birth can be initiated prior to gender-affirming hormone treatment. Hormone therapy can be initiated with a referral from a qualified mental health professional or another health professional appropriately trained in behavioral health and able to assess GI and the eligibility and readiness of the patient for such therapy. WPATH SOC v8 stresses the importance of multidisciplinary evaluations prior to somatic gender-affirming treatments in order to rule out any conditions that would call the diagnosis of GD into question or indicate risks associated with the desired gender-affirming treatments. If any other such condition is present, it should be adequately addressed so that the desired treatments may be safely initiated. Previous versions of the SOC specified minimum durations of living in the experienced gender role prior to the initiation of hormonal therapy, but beginning with version 8 makes no specification in this regard. The WPATH SOC v8 suggests 1 year of continuous gender-affirming hormone therapy (unless contraindicated in an individual) and two referral letters prior to genital surgery. The letters must document persistent GI and the capacity to make a fully informed decision and give consent for treatment. If any medical or mental health concerns are present that may compromise the safety or safe adherence with the desired treatments, they must be adequately assessed and treated.

The WPATH SOC provides flexible guidelines, not rigid rules. For example, individuals assigned female at birth may elect mastectomy and perhaps male breast construction prior to presenting socially as male. Further, not all clinicians follow the WPATH SOC. Consequently, adults who have the capacity to give informed consent may receive gender transition treatments because they satisfy the qualifying criteria of the treating clinicians. These criteria vary among clinicians and clinics. Reviews that have graded the quality of evidence relating particular components of the WPATH SOC to outcomes have concluded that psychotherapy prior to transition is associated with a good outcome. A majority of insurers and providers of gender-affirming treatments may state that they follow WPATH SOC guidelines; however, they may not follow them precisely, creating uncertainty about which gender-affirming treatments are actually covered. Mental health professionals should address this possibility with patients preparing for gender-affirming treatments and encourage them to review this matter with their medical and surgical providers and insurers.

Treatment of Prepubescent Children

Working with children with GD can be considered to follow one of three approaches, each of which will be discussed in turn. None of these approaches entail hormonal or surgical interventions. The first approach focuses on working with the child and caregivers to lessen GD and to decrease cross-gender behaviors and identification. This approach is based upon the assumption that the child's self-esteem can be best served by improved social integration, including positive relationships with same-sex peers, expected to come with decreased gender atypicality. Since GD that persists into adolescence is more likely to persist into adulthood and manifest as transsexuality, this approach has been pursued by some with the goal of inducing desistence prior to adolescence; however, no empirical evidence suggests that is a realistic goal. Persistence is considered to be an undesirable outcome by some but not all clinicians who work in this area. A variety of reasons are cited for considering persistence undesirable, including social stigma as well as the likelihood persistence will eventually entail hormonal and surgical procedures with their associated risks and costs. Critics of this approach have likened it to so-called *sexual orientation conversion efforts (SOCE)* or *reparative therapies* of homosexuality, labeling it as *gender identity conversion efforts*. However, unlike SOCE practices, this clinical approach to children with GD is accepting of adult homosexual outcomes. It has, nevertheless, been legislatively defined as conversion therapy and banned in many jurisdictions.

A second approach, often referred to as *the Dutch approach* because it was developed in the Netherlands, is to remain neutral with respect to gender identity outcome and to not target gender identity and gender-atypical behaviors for change. Also referred to as *watchful waiting,* the goal is to allow the developmental trajectory of gender identity to unfold naturally without pursuing or encouraging a specific outcome. This approach entails combined child, parent, and community-based interventions to support the child in navigating the potential social risks. This approach is premised on evidence that GD diagnosed in childhood usually does not persist into adolescence and beyond and on the lack of reliable markers to predict in whom it will or will not persist. This approach aims to avoid damaging the child's self-esteem by risking conveying to them that their likes and dislikes, behaviors, and mannerisms are somehow intrinsically wrong. This approach may also entail assisting the child in mastering the cognitive, emotional, and behavioral tools for coping with the social stigma of gender diversity.

A third model, referred to by its practitioners as the *gender affirmative approach,* entails affirmation of the child's expressed-gender identification by mental health professionals, family members, and others. Thus, the child may be supported in socially transitioning to a gender role that affirms their experienced gender, with the option of age-appropriate endocrinologic and surgical interventions if GD persists. The rationale for supporting transition before puberty is the belief that a transgender outcome is to be expected in some children and that these children can be identified so that primary caregivers and clinicians may opt to support early social transition. Since childhood transition is done solely at a social level without medical intervention until puberty, some assert that children who transition this way can revert to their originally assigned gender if necessary.

Reservations regarding this approach include that the peer-reviewed literature does not support the view that reliable clinical markers exist to distinguish children whose GD continues into adolescence and adulthood from those where it does not; as well as some studies showing that a social transition in childhood may increase the likelihood of GD's persistence and the need for hormonal and or surgical interventions. In addition, individual case reports suggest that after transitioning in childhood, reverting to the birth-assigned gender may entail stressful social complications.

An APA Task Force on Treatment of GID published in 2012 identified the major tasks for mental health professionals working with children referred for gender concerns. These include accurately evaluating the gender concerns that precipitated the referral; accurately diagnosing any gender identity–related concerns in the child according to the criteria of the most current DSM; accurately diagnosing any coexisting psychiatric conditions in the child, as well as problems in the parent–child relationship, and recommending appropriate treatment; providing psychoeducation and counseling to the caregivers about the range of treatment options and their implications; providing psychoeducation and counseling to the child appropriate to their level of cognitive development; when indicated, engaging in psychotherapy with the appropriate persons, such as the child and/or primary caregivers, or to make appropriate referrals for these services; educating family members and institutions (e.g., daycare and preschools, kindergartens, schools, churches) about gender diversity and GD; and assessing the safety of the family, school, and community environments in terms of bullying and stigmatization related to gender atypicality and to address suitable protective measures.

Kim and Jan are identical twins who were assigned male at birth. Their mother's pregnancy and delivery were unremarkable. Starting at age 2, both children began to exhibit strong atypical gender interests. They preferred playing with girls' dolls and rejected stereotypical boys' toys. As they got older, they liked to play dress-up with their mother's clothing, sometimes wrapping their heads with towels to simulate long hair. Both insisted that they were girls. They preferred to urinate sitting down. Although the parents initially thought their feminine interests would fade away with time, when the children were 5 years old, they sought professional consultation at a gender clinic in the major metropolitan center where they lived.

Both children were given a DSM-5-TR diagnosis of GD in children. The clinic discussed treatment options that ran the gamut from discouraging all cross-gender behavior at one extreme to the possibility of socially transitioning the children to live and be publicly identified as girls. The parents felt that inhibiting the atypical gender interests of their children was too harsh but were not at all comfortable with the idea of social transition, given that it was not clear at the time whether the GD of either child would desist or persist. They opted for what is known as the Dutch approach or watchful waiting. They would be identified publicly as boys with gender-atypical interests, and an effort was made not to interfere with the unfolding of either child's gender outcome. This entailed much psychological support for the parents, some members of their extended family, and occasional consultation with school officials.

At age 10, Kim told the parents that he no longer thought of himself as a girl. At age 14, he came out to his parents as gay. Jan, on the other hand, continued to feel like a girl. At age 12, as puberty began to approach, Jan became very panicky about anticipated bodily changes, and her parents approved of treating her with puberty-suppressing drugs. Her GD never remitted, and when she turned 16, Jan was treated with feminizing hormones.

At age 18, she began seeking consultation to explore surgical treatments.

Treatment of Adolescents

Unlike previous versions of the SOC, v8 includes a chapter specifically devoted to adolescents. In addition, it has removed minimum age requirements for gender-affirming medical care but strengthened the criteria for treatments with the aim of allowing each adolescent the opportunity to receive individualized gender-affirming treatment at the appropriate time. Management of GD that has persisted from childhood is more straightforward than management of GD with later onset, especially when late onset occurs in the context of recent psychological trauma or co-occurring psychopathology. Adolescents with recent onset should be screened carefully to detect the emergence of the desire for gender transition in the context of trauma as well as for any disorders such as schizophrenia, mania, or psychotic depression that may produce gender confusion. When present, such psychopathology must be taken into account in assessing the adolescent’s desire to transition as well as how supportive to be of that desire. The presence of significant psychopathology does not preclude transition but suggests that one should proceed more slowly in establishing the diagnosis of GD as well as ensuring that the psychopathology is treated and controlled to the extent that it will not interfere with adherence to a safe transition plan. Even the presence of a disorder with psychotic features does not exclude a GD diagnosis if the gender concerns persist when the psychosis remits. In addition, ASDs may occur with increased frequency in individuals with GD. Impaired abilities to articulate inner experiences and to assess how they are perceived by others, together with cognitive rigidity and an intolerance of ambiguity, may present special difficulties in gender identity formation in individuals with ASDs. While these limitations do not preclude gender transition in those with ASDs, they, nevertheless, present challenges both in the assessment and treatment of GD.

With the beginning of puberty, the development of the secondary sex characteristics of the gender assigned at birth often triggers or exacerbates the anatomical dysphoria of adolescents with GD. In the last three decades, the option has become available for patients approaching puberty with severe GD and minimal, if any, coexisting psychopathology to have puberty suspended medically in order to prevent or to minimize the development of unwanted secondary sex characteristics, some of which cannot be fully reversed with subsequent hormonal or surgical therapies. Many adults who transitioned gender without the benefit of pubertal suppression express regret over the irreversible body changes that occurred during puberty. Withholding puberty suppression for adolescents is not a neutral option as it can prolong and exacerbate distress, and by allowing pubertal changes of the gender assigned at birth to proceed, contribute to a gender-atypical appearance that could provoke abuse and stigmatization. Current evidence suggests that pubertal suspension can be done for a period of up to several years, during which time the patient, in consultation with clinicians, can decide whether it is preferable for the adolescent to revert to living in the role of the gender assigned at birth or to continue gender transition with gender-affirming feminizing or masculinizing hormone therapy. There are currently few data regarding the best timing for initiating hormone treatment in adolescents, and no studies comparing outcomes when such treatment is initiated in adolescence as opposed to adulthood. In those with DSDs who have been gonadectomized, puberty consistent with the adolescent’s experienced gender is generally induced at the time their peers are entering puberty. One study of carefully selected individuals in the Netherlands, however, found that, as assessed by satisfaction with surgery and lack of regrets, the outcome was generally better in individuals who initiated reassignment as adolescents compared to those who initiated reassignment as adults. A longitudinal follow-up study by the same group found that when pubertal suppression was employed in very carefully selected minors, following age-appropriate pubertal induction and GCS in adulthood, subjects scored as well or better than the general population on measures of psychological and social adjustment.

The WPATH SOC v8 requirements for puberty-suppressing hormones are that the adolescent reached Tanner stage 2 of puberty; the diagnostic criteria of GI as per the ICD-11 have been met in situations where a diagnosis is necessary to access care; the experience of GI is marked and sustained over time; the adolescent demonstrates the emotional and cognitive maturity required to provide informed consent/assent; and any mental health concerns that could interfere with diagnosis or capacity to consent/assent have been addressed. Parents/guardians should be involved in the process unless their involvement is determined to be harmful to the adolescent or not feasible. According to the WPATH SOC v8, genital surgery should not be carried out until patients demonstrate the emotional and cognitive maturity required to provide informed consent/assent for treatment and have had least 12 months of gender-affirming hormone therapy or longer, if required, to achieve the desired surgical result for gender-affirming procedures. They must have also been sufficiently informed of the potential benefits, limitations, and risks of the desired treatment in order to give informed consent/assent. Chest surgery in adolescents assigned female at birth can be carried out earlier than genital surgery, but preferably after “ample time of living in the desired gender role” and after 1 year of testosterone treatment.

Treatment of Adults

Transgender people are sufficiently commonplace that even adult psychiatrists whose practice does not focus on gender diversity may encounter patients who are transitioning gender or contemplating gender transition. Thus, even psychiatrists who are not gender specialists should be prepared to provide informed and respectful care to gender-diverse patients, including accurate diagnostic assessments and culturally attuned treatment plans that include not only the provision of immediate care but the arrangement of necessary referrals for those who are, or who are contemplating, transitioning gender. All clinicians should be aware of the federal, state, local, and regulatory agency policies that pertain to the provision of care to transgender and gender-diverse patients in their workplace. Adult patients coming to a gender identity clinic often present with straightforward requests for hormonal and surgical gender reassignment. When GD is severe and intractable, gender reassignment is often the best solution.

Mental health professionals who work with individuals who plan to transition using hormonal and/or surgical treatments or who are in the process of doing so need to be knowledgeable about these treatments, particularly their mental health implications. All should be aware that hormonal regimens may lead to infertility and should receive appropriate counseling and referrals if preservation of reproductive potential is desired. Those assigned male at birth should be aware that estrogen treatment will cause erectile dysfunction as well as atrophy of the testes and penis.

As discussed previously in this chapter, which, if any, medical and surgical procedures to employ in one's transition plan varies from one individual to the next. Similarly, some seek mental health services for psychological support or to assist in decision making, while others do not.

FTM transition usually includes the use of androgens, which produce male secondary sex characteristics, including beard growth and male distribution of body hair, possible alopecia, deepening of the voice, and coarsening of the facial features and skin. Androgen administration also enlarges the clitoris, often to the extent that metoidioplasty becomes feasible. MTF transition often consists of both estrogen administration in conjunction with agents that either suppress androgen levels or interfere with androgens' actions. Estrogen effects include breast development and feminizing changes to skin and hair, although, for many who transition after completion of male pubertal development, depilation will be needed. Surgical reduction of the laryngeal cartilage or facial surgeries may be needed for a convincing feminine appearance. The use of hormonal preparations is much more effective in "adding" physical sexual characteristics than in "subtracting" those that have already developed with natural puberty. Utilization of either androgens or estrogens carries the potential for both added health risks and, in some cases, physiologic benefits. Just as cisgender men and women have different profiles of health risks, some of which are related to differences in sex hormones, gender-affirming hormonal regimens may shift some risks in the direction of an individual's affirmed gender. Similarly, normal ranges for some laboratory bloodwork measures also vary slightly between cisgender men and women and are subject to shift with gender-affirming hormone treatment. Psychiatrists may prescribe and monitor the effects of hormonal preparations used in gender transition, but this aspect of transition is best managed by endocrinologists or primary care physicians with training in this area. All of the treating clinicians should be aware of potential psychological effects, including the emotional changes that may occur with the use of either androgen or estrogen supplementation. Increased libido usually occurs with androgen use. Some who transition MTF also experience a stronger interest in sex, perhaps due to increased self-confidence after physical feminization. Often, individuals who are transitioning benefit from ongoing psychiatric care. In addition to the psychotherapeutic work involved in the context of life-changing experiences, psychiatric care may include monitoring the psychiatric effects of hormone use along with the prescribing physician and monitoring adherence with medical monitoring. Safer sex information, and instruction in self-protective negotiations in sexual settings, should be provided by the psychiatrist if this has not been done by the prescribing clinician. This information should be tailored to the needs and experiences of transgender persons.

Surgeries for purposes of gender transition include breast and chest ("top") surgeries as well as genital and gonadal ("bottom") procedures. The goal of masculinizing top surgery is not mastectomy, as would be performed for the treatment of cancer of the breast, but the creation of a natural-appearing male chest. Some transgender women have breast augmentation surgery due to achieving minimal breast development with hormonal treatment alone. Many adults undergoing feminizing genital surgery receive penile inversion vaginoplasty with clitoroplasty, labiaplasty, and orchiectomy.

Feminizing genital surgery can consist of either metoidioplasty with limited scrotoplasty or more extensive surgery, including phalloplasty with grafted tissue from another body site, urethral extension, scrotoplasty, and vaginectomy. Hysterectomy and oophorectomy are usually performed in either case. Transgender masculine patients may also seek oophorectomy as a gender-affirming procedure or for medical indications. In addition to electrolysis or laser treatments for removing unwanted facial hair, many transwomen also benefit from voice training that focuses on five parts of speech: pitch, intonation, volume, articulation, and resonance to improve their female gender expression. Some transgender adults may seek out facial feminization or masculinization surgery as well as surgeries to masculinize or feminize the voice. Voice coaching is usually recommended prior to surgeries. Transgender women may also desire a tracheal shave to reduce the prominence of the Adam’s apple. Feminizing voice surgery is sometimes performed at the same time as the tracheal shave.

In order to give truly informed consent, patients should be able to describe the procedures they will receive in reasonable detail, including realistic outcomes and risks, as well as what, if any, convalescent period and medical follow-up will be involved. To demonstrate readiness for each step of the treatment, they must also demonstrate the capacity to adhere to its demands, including necessary medical monitoring and postsurgical care.

Maria, who was assigned female at birth, reported being a tomboy as a child. In childhood, she had both boys and girls as playmates, but her best friends were boys. She enjoyed sports and boy's games and had no interest in dolls. She resisted wearing skirts and dresses and preferred boyish clothing. She reported feeling different from other girls, a feeling that intensified when she entered puberty, at which time she wore loose-fitting shirts to conceal breast development and became markedly distressed with the onset of menses. She recalled wishing she had been born male. From her earliest awareness of sexual attractions, they were directed toward girls, and by the age of 15, she began to label herself a lesbian and began to socialize with lesbian and gay teens. Nevertheless, she felt different from the other lesbians in a way she could not quite describe. She wore masculine clothes, baggy shirts, concealed her breasts by binding them, and kept her hair cropped short.

In her second year of college, she began dating a woman with whom she fell in love, and the two began living together as a couple. In the relationship, she realized she experienced herself as a man rather than as a lesbian, began to explore transgender websites, and enrolled in a human sexuality course at college. Now using male pronouns, *he* found the identity of *transgender man* aptly labeled his experienced gender, began to think of transitioning, and discussed the possibility with his partner, who was supportive. He changed his name to Mark, began to wear only male clothing, and requested that family, friends, and colleagues address him as a man. He experienced a level of authenticity living as a man that he had not previously experienced as a lesbian. He referred himself to a medical school–affiliated clinic that offered hormonal and surgical gender confirmation services. After careful evaluation, a transition plan was formulated, which included a mastectomy and male breast construction. Testosterone therapy for lowering the voice, beard growth, and masculinizing the body was temporally delayed to allow time for Mark's ovaries to be stimulated to harvest eggs for cryoprotection to allow future reproduction (with his partner expected to carry the pregnancy after fertilization with donated sperm). He also entered into individual and couples psychotherapy. Upon starting testosterone therapy, his menses stopped, his voice deepened, facial and body hair grew, his sex drive increased, and his clitoris enlarged. As eggs had been harvested, Mark elected to undergo hysterectomy and oophorectomy sooner rather than later. He also elected metoidioplasty. Four years later, Mark had graduated college, was working full time, and the couple had their first child.

The APA Task Force on GD identified the following tasks of mental health professionals working with adults with GD: assessing and diagnosing patients' gender concerns according to DSM criteria and assuring that these are appropriately addressed; assessing and correctly diagnosing any coexisting psychopathology and assuring that it is addressed adequately; distinguishing between GD with concurrent psychiatric illness and gender manifestations that are not part of GD but epiphenomena of psychopathology; engaging in psychotherapy with gender-diverse individuals as indicated. This includes identifying the elements that should be addressed in therapy, including the impact of discrimination and stereotyping; ensuring that individuals who are in the process of transitioning, or who are considering or planning to do so, receive counseling from a qualified professional about the full range of treatment options and their physical, psychological, and social implications including both their potential benefits and the full range of potential limitations (e.g., loss of reproductive potential and possibilities for preservation of gametes and assisted reproduction), risks and complications; ascertaining eligibility and readiness for hormone and surgical therapy or locating professionals capable of making these ascertainments to whom the patient may be referred; and educating family members, employers, and institutions about GD.

Treatment of Individuals with DSDs Including Somatic Intersex Conditions

Some individuals with DSDs, in a proportion that varies greatly with the syndrome and assigned gender, become dysphoric in their assigned gender and may desire to transition. In DSM-5-TR, these individuals can meet criteria for the diagnosis of GD, although they were categorically excluded from the diagnosis of GID in previous versions of the DSM (but could be given the diagnosis of GID not otherwise specified). A variety of issues in the clinical care of individuals with DSDs require the expertise of mental health professionals. The clinical options and decision-making processes that bear on gender transition and reassignment overlap to some extent regardless of the presence or absence of a DSD. When a DSD is present, however, there have been fewer barriers to legal gender reassignment, and the barriers to hormonal and surgical treatments in conjunction with gender reassignment are lower. This is because some individuals with DSDs, particularly those involving somatic intersex conditions, will have been gonadectomized prior to adolescence as part of routine treatment (e.g., to reduce the risk of malignancy that is associated with some gonadal abnormalities) and thus will have been rendered sterile. They will also require the age-appropriate administration of exogenous hormones to induce puberty. Thus, concerns of gonadectomy, pubertal suppression, lifelong dependence on exogenous hormones, and infertility differ from those patients without a DSD.

Major areas of involvement of psychiatrists and other mental health professionals in the care of individuals with DSDs and GD include the evaluation of gender identity and the assessment of incongruences, if present, between gender identity and assigned gender; decision making regarding gender reassignment; psychotherapy to address significant GD in individuals with a DSD who do not transition gender; psychological aspects of the endocrine management of puberty in the context of gender reassignment; and psychological/psychiatric aspects of genital surgery in the context of gender reassignment. Whether or not GD is present, individuals with DSDs have often been subjected to a variety of significant stigma due to their condition and may benefit from psychotherapy to address it.

Some individuals may identify as being intersex in the absence of any physical or medical evidence of a DSD. As some DSDs require ongoing medical treatment or screenings, sometimes as a result of their treatment history, it is important that clinicians clarify whether they are receiving needed care. For example, some DSDs increase the risk of particular malignancies, and affected individuals may require ongoing monitoring, while some individuals with DSDs have been gonadectomized and require hormone replacement therapy to prevent osteoporosis. Others with some forms of congenital adrenal hyperplasia require ongoing treatment to prevent salt-wasting and hypotensive crises. It is, therefore, important to clarify if an individual who identifies as intersex has a DSD that requires ongoing medical treatment and if they are engaged in such treatment. Medical referrals should be offered in cases of uncertainty. Importantly, referrals can be made without challenging a patient’s intersex identity by stating that a referral is needed to determine whether they have a condition that requires ongoing treatment. In addition, if a mental health provider employs the DSM-5-TR GD specifier, “with a disorder of sex development,” the patient’s specific DSD diagnosis must be recorded and coded.

Other Clinical Issues

The 2011 IOM report on the health of LGBT people drew increased attention to the fact that compared to the general population, LGBT populations experience increased violence, barriers to health care, and poorer physical and mental health. The report further pointed out the tendency of studies to lump LGBT populations together rather than studying them separately, greatly limiting knowledge as to how disparities affect each population individually. This is particularly true for the transgender population, the smallest segment of the LGBT community. The report called for all federally funded national health surveys to include queries regarding sexual orientation and gender identity (SOGI) so that these disparities could be characterized and addressed in different sexual and gender minority populations. Reports based on these surveys consistently confirm marked health disparities in gender minority populations.

To date, however, with 27,715 respondents, the 2015 U.S. Transgender Survey (USTS) conducted by the National Center for Transgender Equality and the National LGBTQ Task Force is the largest survey devoted to the lives and experiences of transgender individuals. Findings from the online survey are overall similar to the U.S. National Transgender Discrimination Survey (NTDS) conducted in 2010 with 6,450 participants. Participants in both surveys endorsed a high rate of avoiding health care due to a history of discrimination in health care settings. For example, in the USTS, a third who had seen a provider reported negative experiences in the receipt of care, such as being verbally harassed or denied treatment due to being transgender, while 23% reported they had avoided seeking health care in the prior year due to fear of being mistreated and 33% said they did not see a health care provider during the past year because they could not afford to do so. These barriers to care greatly exacerbate the health disparities seen in the transgender community.

Violence. Transgender people are often targeted for violence based on their nonconformity with gender norms and/or their perceived sexual orientation. Assaults against transgender people, particularly transgender women of color, tend to be particularly violent, and the Human Rights Campaign has shown that a high proportion of homicides in the United States are antitransgender hate crimes. In the USTS, approximately 10% who were out to their immediate family reported having experienced violence within the family because they were transgender, and many were forced to leave home. Over half who reported being perceived as transgender while in school reported abuse, including verbal harassment, being physically or sexually assaulted because they were transgender, and 17% reported dropping out of school to escape abuse. Nearly half reported having been sexually assaulted at some time in their life, and, in the year prior to the survey, 30% of those who were employed reported having experienced difficulties at work due to being transgender, including being fired, denied promotion, or being verbally harassed. In addition, 31% reported having experienced mistreatment in the past year in a place of public accommodation, with 2% reporting physical assault.

As adults, transgender individuals report increased rates of childhood maltreatment and abuse which are predisposing factors for the later onset of psychiatric symptoms and disorders, including depression, post-traumatic stress disorder, and substance abuse. In the NTDS, those who endorsed a transgender or gender-nonconforming identity in grades K-12 reported extremely high rates of harassment (78%), physical assault (35%), and sexual violence (12%). Harassment was so severe that 15% left a school in K-12 settings or in higher education. Perpetrators of harassment and abuse were reported to be teachers as well as peers, with teacher perpetrators being associated with worse outcomes with respect to HIV infection and substance abuse. Transgender individuals are also among the groups most likely to be impacted by intimate partner violence.

Suicide. There is evidence indicating that transgender populations are at increased risk for suicide. Because gender identity is not systematically recorded at the time of death, the number of transgender deaths from suicide (or any other cause) is not known. However, high rates of suicide have been reported among individuals receiving medical interventions for gender transition. Nondisclosure of transgender status is associated with a lower risk of suicide attempts, possibly because hiding protects against rejection, discrimination, and victimization, which are otherwise strongly linked to suicide attempts in transgender populations. In surveys, 25% to 43% of transgender adults have reported lifetime suicide attempts.

In the NTDS, 41% of respondents reported attempting suicide compared to 1.6% of the general population, with rates rising for those who lost a job due to bias, had a history of being harassed/bullied in school, had low household income, or were the victim of physical assault or sexual assault. Discrimination was pervasive throughout the entire sample; however, the impact of antitransgender bias was particularly marked when it was combined with racial discrimination. People of color, in general, fared worse than White participants, with African American transgender respondents faring worse than all others in many areas examined. In the USTS, 39% endorsed having experienced severe psychological distress in the month prior to the survey, and 40% reported a lifetime history of attempted suicide, approximately nine times the national average.

Assessment and treatment of suicide risk in transgender individuals requires practitioners to be familiar with the cultural milieu of their lives. Not only should clinicians be cognizant of the impact that antitransgender or *transphobic* attitudes can have on normal psychosocial development, but they must also recognize extreme situations that may arise. This requires awareness of and asking about events that a patient—perhaps in the closet or fearing lack of support from a medical/psychiatric authority—may not offer spontaneously. For example, is a child, adolescent, or adult being bullied or harassed for gender-atypical behavior? Has an adolescent or adult been rejected after coming out to a family member or friend? Has an adolescent been thrown out of their home by unaccepting parents? Is a desperate transgender patient unable to access needed medical care for transition? These are just some examples of the kind of culturally sensitive knowledge clinicians need to access if they are to provide support to this at-risk patient population.

Mental Health. Survey studies have consistently found transgender men and women to report higher rates of substance abuse, suicidal ideation, suicide attempts, and stress-related psychiatric disorders (e.g., anxiety, depression, and somatization) compared to national norms. As noted, many report misusing substances to cope with stigma and discrimination due to their gender expression. Similarly, self-reported social stigma and discrimination have been found to be correlated with the degree of psychological distress. These findings based on self-report are similar to findings based on examining the electronic health records of transgender U.S. veterans who received care through the Veterans Health Administration. Specifically, transgender veterans were found to have an increased prevalence of post-traumatic stress disorder, depression, alcohol abuse, and suicidality. Examination of mortality data revealed that veterans with transgender-related ICD-9 diagnoses have an increased suicide rate, with the average age of suicide being 49.4 years.

Transgender individuals and those with GD may also have psychiatric disorders that are independent of their gender concerns, and while even serious mental illnesses such as major depression, bipolar disorder, borderline personality disorder, and schizophrenia are not absolute contraindications to gender transition, they must be adequately treated so as not to interfere with adherence with the transition regimen. Very importantly, the manifestations of coexisting disorders should not be mistaken for manifestations of GD that will resolve with the transition. Those in transition should understand that coexisting psychiatric disorders are very likely to persist and require treatment after transition.

Medical Illness. Little research has focused specifically on physical health disparities in transgender populations beyond sexually transmitted infections among transgender women and the effects of hormone therapy on physical health. There have been reports of increased risk of venous thromboembolic disease associated with feminizing hormone therapy, but this appears to have been primarily associated with the use of ethinyl estrogen, found in birth control pills and no longer used for gender-affirming treatment in the United States. There have also been reports of elevated prolactin levels associated with feminizing hormonal therapy; however, this may be specifically linked to the use of cyproterone acetate as an adjunctive antiandrogen and has not been reported when spironolactone is used to block androgen action or when gonadotropin-releasing hormones are employed to decrease androgen production. As gonadal hormones are needed for the maintenance of bone mineral density, it is important, especially while taking antiandrogen therapy or after gonadectomy, for transgender patients to adhere to their gender-affirming hormone replacement regimens. A case-control study of disparities in over 5,000 transgender veterans found an increased prevalence of 17 out of 18 medical diagnoses, including chronic obstructive pulmonary disease, diabetes mellitus, and HIV infection. Many of the observed disparities are likely the result of barriers to health care in transgender individuals and not their gender-affirming regimens. Childhood and adolescence are times of good physical health. Thus, studies exploring the physical health of children with GD are lacking.

Children. Primary modes of therapy utilized in working with children with GD include individual insight-oriented psychoanalytic or psychodynamic psychotherapy; protocol-driven psychotherapy such as behavior modification; parent and peer relations-focused therapy; and parent and child therapeutic groups. Additional interventions include support groups for primary caregivers, community education through websites and conferences, school-based curricula, and specialized youth summer camps. The primary focus of intervention is often the primary caregivers. Depending on the treatment approach chosen, work may include parenting support and psychoeducation, careful guidance regarding behavior modification efforts and their potential to damage self-esteem, and instruction in techniques for building self-acceptance and resilience in the child. Some interventions are multifaceted and involve the school and community as well as the child and family. These include diversity education and steps to prevent bullying. As stated, psychotherapeutic efforts to change the gender identification in prepubescent children with GD have provoked angry responses in the LGBT community, with some arguing that they represent a form of conversion or reparative therapy and with some jurisdictions legislatively defining them as such. Given that most children with GD may experience spontaneous remission of their symptoms, it is not clear how, if at all, these therapeutic interventions influence the rate of desistence.

Adolescents and Adults. While GD in adolescents or adults sometimes remits, there is no convincing empirical evidence for remission in response to psychotherapeutic interventions, although there are anecdotal reports. Consequently, as such approaches have not been well studied in the last century, let alone proven, they are currently not considered effective by mainstream psychiatry and other mental health professions. This lack of psychotherapeutic responsiveness in part underlies the longstanding approach of assisting gender dysphoric individuals with transition rather than trying to change their gender identity. This entails supportive therapy and psychoeducation to ensure that the individual understands the long and often difficult process of a physical gender transition and has fully explored other options, including not transitioning (and living as a homosexual person if one is sexually attracted to members of their sex assigned at birth), transitioning socially without medical or surgical intervention, or selecting which endocrine and surgical alternatives to pursue. Psychotherapy can assist patients in exploring options, including social, hormonal, and surgical, for finding authenticity in their experience and expression of gender.

ETHICAL AND LEGAL ISSUES

Legal Change of Gender

Depending on what country and jurisdiction they live in, transgender individuals face a range of different regulations if and when they seek a change of gender on legal documents. Some U.S. states (Kansas, Tennessee) currently refuse to amend the gender on birth certificates; Tennessee's statute specifically forbids amending the sex designation on birth certificates. A majority of states permit one's name and sex to be changed on birth certificates, either through amending an existing birth certificate or issuing a new one; however, GAS is a prerequisite in many states, some of which require documented infertility. All U.S. states allow a legal change of gender on drivers' licenses, although requirements for doing so vary from state to state. Countries without marriage equality may not recognize the marriage of two individuals whose identity documents show they are the same gender. For example, a transgender woman who had not changed the gender marker on her identity documents might not be able to marry a man, whereas, if she had changed her identity documents, she would not be able to marry a woman. Surviving transgender spouses have been denied inheritances and surviving spousal rights in many cases.

In the United States, the gender designation on federally issued documents such as passports can now be changed with a single physician's letter that can be issued without requiring either hormonal or surgical treatments. However, some countries will not allow legal changes of gender unless the individual has been rendered infertile via surgical means.

Antidiscrimination Protections

Title VII of the U.S. Civil Rights Act prohibits discrimination on the basis of sex which has been interpreted in several federal cases since 2004 as extending to claims of discrimination based on gender identity or failure to conform to stereotypical notions of masculinity or femininity. In 2012, the Equal Employment Opportunity Commission, the federal agency in charge of enforcing employment discrimination laws, declared that antitransgender bias was sex discrimination under Title VII. In 2014, Attorney General Eric Holder issued a memo clarifying that the Justice Department will no longer assert that Title VII's prohibition of gender discrimination does not encompass gender identity, per se. In 2020, in the case of Bostock v. Clayton County, Georgia, the U.S. Supreme Court decision declared that Title VII workplace protections applied to transgender (and sexual orientation) status. Currently 25 U.S. states, the District of Columbia, Guam, Puerto Rico, and the U.S. Virgin Islands have statutes that protect against discrimination on the basis of sexual orientation or gender identity in both the public and private sector.

In 2021, President Biden issued Executive Order 13988 on Preventing and Combating Discrimination on the Basis of Gender Identity or Sexual Orientation requiring each federal agency to fully implement statutes that prohibit sex discrimination and policy set forth in the order. The Department of Housing and Urban Development then issued a memorandum clarifying that the Fair Housing Act's prohibition against sex discrimination in housing extends to discrimination on the basis of actual or perceived sexual orientation or gender identity. Currently, the majority of U.S. states do not provide state-level antidiscrimination protections for transgender individuals.

Gatekeeping and Informed Consent Models

Many countries with national health care systems require mental health professionals to act as *gatekeepers* of transition services for transgender people. This gatekeeping function is ostensibly to reduce the incidence of post-transition regrets, particularly for those undergoing irreversible surgical procedures. Yet there is a somewhat irrational *gender policing* quality to this requirement since few other surgical procedures, including those considered high risk, require psychiatric evaluation and approval. Finally, there is no empirical evidence that all prepubescent children who socially transition but then desist can simply transition back to the gender assigned at birth without complication. Given the complexity involved in the first social transition, it seems unlikely that transition back to the original gender would not carry its own set of risks. Definitive answers are unlikely to be forthcoming promptly given both the small numbers of children who transition gender and the ethical considerations that preclude randomized controlled trials. The informed consent model provides multiple opportunities to prepare parents and patients for the choices they must make with a realistic understanding of the range of outcomes. Some clinics in the United States now employ an "informed consent model" for transgender endocrine care that differs from the gatekeeping model by a focus on informed consent as the threshold for the initiation of gender-affirming hormonal therapy. While less emphasis is placed on mental health care unless a patient requests it, when significant mental health concerns are present that may diminish the patient's ability to safely adhere to treatment, they need to be addressed before hormones are prescribed, even in this model.

Access to Care for Incarcerated Individuals

The Prison Rape Elimination Act (PREA) was passed by the U.S. Congress in 2003 and became effective in 2012. This act specifies that individuals entering prison who identify as transgender should not be placed in gender-specific facilities, housing units, or programs based solely on their external genital anatomy but that their own views with respect to safety will be taken into consideration in housing. How PREA is enforced outside of federal prisons varies from state to state. Similarly, access to gender-affirming hormones and surgeries varies across jurisdictions. In recent years, transgender advocacy groups have had some success in lawsuits against prison facilities for denying access to hormone treatment, arguing that denial of such needed medical treatment constitutes “cruel and unusual punishment.” Many carceral facilities now have policies to continue gender-affirming hormones that were started prior to incarceration, while others arrange for inmates to be assessed for GD and started on affirming hormones after incarceration. In 2017, California became the first state to provide GAS for an inmate, and in 2019, the 9th Circuit Court of Appeals ruled that the state of Idaho must provide GAS for an inmate, and the surgery was done in 2020. Other prison systems now have programs for assessing inmates’ eligibility and readiness for gender-affirming surgeries. In 2023 the first inmate in the custody of the federal Bureau of Prisons, received GCS.

Ethical and Legal Issues in Child Treatment Controversies

Clinical approaches to gender-diverse children raise many as yet unanswered ethical questions. For example, some transgender advocates maintain that clinical attempts to prevent transsexuality in prepubescent gender-diverse children, no matter how well meaning, are always unethical. There are presently no controlled studies that demonstrate that discouraging intense, atypical gender behavior and interests in childhood does, in fact, reduce persistence or prevent transsexuality. Further, rigorous studies are not feasible due to the ethical concerns they would raise together with the fact that parents would be unlikely to allow the treatment of their child to be assigned at random. As previously stated, there are no reliable indicators to distinguish children whose GD will continue into adolescence from those whose GD will not. Since no clinician can accurately predict the future gender identity of any particular child, it is reasonable to assume that efforts to discourage gender-atypical play and identifications may be experienced as hurtful and possibly even traumatic by children whose GD continues into adolescence and adulthood. Also, it is possible that opposing a wish to explore cross-gender expression is harmful to some children, and not just persisters. Whatever the outcome regarding their transgender behavior or identity, these children may internalize disapproving attitudes toward GNC behavior and expression (*transphobia*) with possible consequences for adult development. Is it ethical to delay the social transition of children in whom GD will persist in order to prevent possible psychological harm to those who will desist? Put another way, are the children who will grow up to be transgender being subjected to unnecessary stress in order to preserve the well-being of those who will not? Finally, there is no empirical evidence demonstrating that a prepubescent child who is permitted to socially transition but then desists can simply and harmlessly transition back to the gender assigned at birth. Given the complexity involved in the first social transition, should the claim that transition back to the original gender is entirely without risks and pitfalls be questioned? In the absence of empirical studies, is permitting early social transition without a verifiable system of distinguishing future persisters from desisters ethical? Further, would conducting such empirical studies even be ethical?

While clinicians debate some of the ethical questions outlined above, forces outside the clinical setting are weighing in. In 2020, a U.K. lawsuit against the Tavistock Clinic's Gender Identity Development Service (GIDS) in London was heard by the Royal Court of Justice. The Court decided that any medical treatment, mentioning puberty blockers in particular, of a child under the age of 16 would require court authorization. That decision was overturned on appeal in 2021, with the Appeals Court noting "it was for clinicians rather than the court to decide on competence." Nevertheless, in response to complaints about long waiting lists for evaluating new patients, the GIDS is scheduled to be closed in 2024 to be replaced by two regional centers at existing children's hospitals in the United Kingdom.

Also, at the time of this writing, in the United States, at least 16 state legislatures have introduced bills to make it a crime, and in some states a felony, for health care professionals to provide medical or surgical treatment to minors before the age of 18. The rationale for introducing such legislation has been couched in names like “The Vulnerable Child Protection Act” (Florida) or “The Save Adolescents from Experimentation (SAFE) Act” (Arkansas). In 2021, the Arkansas legislature sent their bill criminalizing gender transition services to the Governor, who subsequently vetoed it, calling the legislation an unwarranted intrusion of government into the relationships between health care professionals and their patients. However, his veto was overridden by both houses of the legislature, making Arkansas the first state to pass such legislation. The law was challenged in federal court and, after a trial in 2023, the judge declared “The Court finds that the State has failed to prove that its interests in the safety of Arkansas adolescents from gender transitioning procedures or the medical community’s ethical decline are compelling, genuine, or even rational” and in violation of the U.S. Constitution’s First and Fourteenth Amendments. At the time of this writing, it is likely that the State of Arkansas will appeal.

TRAINING AND RESEARCH NEEDS

Training

Transgender presentations are sufficiently common that even adult psychiatrists whose practice does not focus on gender diversity encounter patients who are transitioning gender or contemplating gender transition. However, GD and gender transition receive little attention in medical school or psychiatric residency curricula. In a survey of deans of medical education at over 100 medical schools across North America, 34% rated coverage of SOGI minority health care as poor to very poor, with only 30% rating it as better than fair. Further, on average, only 5 hours were devoted to training in caring for LGBT patients though out the 4-year medical school curriculum, and only 30% of schools provided any training on gender transition.

In a survey of psychiatrists, many reported difficulty distinguishing GD from “gender confusion” that may occur as an epiphenomenon of psychiatric illnesses, notably personality, mood, dissociative, and psychotic disorders. The authors suggested that GD is likely to be underdiagnosed, leading to inappropriate treatment. These surveys of medical professionals’ training are consistent with the NTDS, in which 50% of transgender respondents believed that clinicians were not aware of their unique needs. In recognition of these deficiencies, calls for increased clinician training in the provision of care to transgender individuals have been made by several distinguished and authoritative bodies, including the Institute of Medicine, the Department of Health and Human Services, and The Joint Commission. Ideally, training in SOGI minority issues, including gender diversity transgender, and GD, should be embedded within the broader curriculum of human sexuality and integrated across all levels of medical school and residency training. SOC v8 recommends all health care professionals working with adolescents have expertise in gender identity development and gender diversity in children and adolescents and the ability to assess capacity for assent and consent, and possess general knowledge of gender diversity across the lifespan. Psychiatric training should include (1) the evolution of concepts of gender, gender diversity, and associated terminology; (2) the evolution of medical approaches to gender diversity, including the changing roles of mental health professionals in transgender health care as reflected in successive versions of the WPATH SOC and the emergence of informed consent models; (3) common child and adolescent presentations; evaluation of gender-diverse youth; assessment and management of any coexisting psychopathology in minors; treatment options, including pubertal suppression; persistence and desistence of GD of childhood; and family concerns; (4) common adult presentations, the process of gender transition and other options for authentic gender expression; assessment and management of concurrent psychiatric illness, and stage of life concerns; (5) mental health assessments for gender-affirming hormones and surgery; (6) presentations, evaluation, and management of GD in patients with somatic intersex conditions; (7)

complex presentations, nonbinary gender identities, and the role of the mental health professional in alternative models of treatment; and (8) relevant jurisdictional and institutional policies including those pertaining to respectful treatment of gender diverse individuals as well as those that affect access to gender transition services. While the goal of psychiatric residency training is not to produce gender specialists, the general psychiatrist, regardless of specialty or work setting, should be prepared to perform a culturally competent initial assessment of gender-diverse individuals, including a formulation based on the current version of the DSM, provide initial treatment, and provide appropriate referrals.

Research

Some future research directions on the origins of gender identity and GD are addressed previously in this chapter. Other areas of research include the following:

1. Identification of health disparities and barriers to care for transgender individuals is a first step toward addressing them. Much of what is presently known comes from convenience samples which are not fully reliable. The U.S. Department of HHS is now gathering systematic data. Larger-scale studies will become possible if both sex assigned at birth and current gender identity are routinely gathered as demographic variables in health care settings and recorded in EHR as recommended by HHS, IOM, and Joint Commission.
2. Mental health disparities, including mood and anxiety disorders, substance abuse, and suicidality, have been detected in studies to date. It is important to research the causes of these disparities and to find effective means of intervention. Considerable research suggests minority stress and discrimination, including harassment and bullying, play a significant role. Emerging research suggests family acceptance and peer support as means of ameliorating the effects of minority stress. More studies are needed to elucidate not only effective means for overcoming the effects of minority stress but to identify the causes of intolerance of gender diversity and to address them.

3. There is a need to compare the quality-of-life outcomes associated with diverse treatment approaches to gender diversity in childhood. Robust experimental designs, however, such as randomized trials in this area, are neither ethical nor feasible. Very few parents would allow the treatment of their child to be randomly assigned. Concern has been expressed that attempts to “normalize” a child’s gender expression may have long-term harmful effects on self-esteem. Longitudinal follow-up studies without randomization could potentially address this issue.
4. More longitudinal studies following pubertal suppression are needed. Recent studies by Dutch researchers found that when puberty suppression was done in very carefully selected minors, following GCS as adults, they scored as well or better than the general population on measures of psychological and social adjustment. More studies are needed to determine if these results will generalize to those receiving this treatment in other clinical settings. Since pubertal suppression is a relatively recent intervention, long-term follow-up studies are needed to rule out long-term risks.
5. What are the roles of mental health professionals in optimally addressing the needs of gender diverse individuals, including those considering, planning, or in the process of transition? Follow-up studies are needed to examine how particular mental health interventions influence long-term adjustment and subjective satisfaction. Matching comparison groups—those treated with particular mental health interventions versus those who were not—for potentially confounding variables, however, would be difficult.

▲ 21.5 Sexual Addiction

MARCY VERDUIN, M.D.

A disorder in which a person's driven sexual behavior is poorly controlled and continues despite harmful consequences has a documented history of more than two millennia. The Pali Canon, the standard scriptures of Theravada Buddhism that were compiled from oral tradition and written in 29 BCE, includes the following passage:

> Then early in the morning the Blessed One, having put on his robes and carrying his bowl and outer robe, went into Savatthi for alms. He saw that most of the people in Savatthi were excessively attached to sensual pleasures, that they lived delighting in, addicted to, infatuated with, fastened to, absorbed in sensual pleasures. Then, on realizing the significance of that, the Blessed One on that occasion exclaimed:
>
> Blinded by sensuality, covered by the net, veiled with the veil of craving, bound by the bond of heedlessness like fish in the mouth of a trap, they go to aging and death like a suckling calf to its mother. [Udana VII.4 Kāmesu Satta Sutta, tr. Thanissaro Bhikkhu]

Psychiatrist Richard von Krafft-Ebing, who published on this topic in the late 1800s, identified this condition as *hypersexuality*, which is generally defined as excessive sexual interest (or urges) or activity. It was an advance over its predecessors, *satyriasis* and *nymphomania*, which are defined as uncontrollable or excessive sexual desire in a man and in a woman, respectively. The definition of *hypersexuality* is more closely related to sexual behavior, which is more objectively observable and quantifiable than sexual desire. In addition, hypersexuality is gender-neutral.

In 1945, the psychoanalyst Otto Fenichel coined the term *sexual addiction* to designate the condition of driven sexual behavior that is under discussion. Whereas excessiveness in the definition of hypersexuality represents a quantitative dimension, the term *sexual addiction* directs attention toward indications of a sexual behavior's adverse consequences and a person's impaired control over the behavior. It also implies a relationship between this disorder and other disorders, the names of which also include the word *addiction*.

The next section addresses terminologic and diagnostic matters that pertain to this condition. Before proceeding, three characters are introduced whose stories give human faces to the clinical abstractions, provide examples of how a condition of driven sexual behavior may look in a person's life, and illustrate the potentially tragic seriousness of the condition. (The characters are fictional and are presented as illustrative examples, not case reports.)

Ronnie, an electrician in his mid-20s, had used alcohol and other drugs heavily in high school. He dropped out of college in his freshman year and went to work in his uncle's electrical contracting business. After a serious accident on the job, while he was intoxicated, he quit recreational use of psychotropic substances.

Over the next several months, he found that his sexual fantasies and urges to masturbate were becoming more frequent and more intense than they previously had been. Since his middle teens, Ronnie had masturbated nearly every night before going to sleep, unless he was having sex with a girlfriend or a woman he had picked up. Some mornings during his first year of being drug-free, Ronnie would get strong urges to masturbate. If he did not act on these urges, he would remain "horned up" all day and would feel restless, distracted, and irritable. Consequently, he began to masturbate in the mornings as well, even though doing so sometimes resulted in his arriving to work late.

Some months later, Ronnie began to get urges to masturbate when he was at work, particularly if he saw a woman at the job site. Again, he found that if he did not masturbate, he would become uncomfortable and unable to focus on his work. No longer sufficiently excited by his fantasies, Ronnie began to watch free online pornographic videos while he masturbated. He also discovered peer-to-peer file-sharing sites from which he could at no charge (but illegally) download better quality, longer, and more varied porn videos.

Before long, Ronnie was masturbating three or four times a day and even more when he felt under stress. He was chronically tired from lack of sleep, had received a second warning about tardiness and inattentiveness at work, and felt disgusted with himself. He tried several times to stop masturbating. But each time, sexual fantasies accompanied by arousal would intrude into his consciousness throughout the day, and he would feel as though he were going to blow up. The only way he knew to free himself from the building pressure was to masturbate. At the beginning of a new sexual relationship, he would delete his collection of pornography and resolve to quit masturbating. Within a few months, though, masturbation would creep in and take over, his sexual interest in his girlfriend would fade, and the relationship would fall apart.

As Ronnie became increasingly bored with familiar porn videos and new ones with the same old plot formulas, he began to accompany his masturbation with increasingly sadomasochistic videos. He also started using telephone sex and online sex-cam services, neither of which were free of charge. When he had “maxed out” his credit cards, he obtained new ones that he soon ran up to their limits. He got behind on his rent, and the power company threatened to cut him off unless he paid his bill.

Socially isolated, deeply in debt, and about to lose his job, Ronnie realized that his preoccupation with masturbation and pornography was ruining his life. But he felt helpless. Meanwhile, he also was beginning to sense that pornography, phone sex, and sex-cams no longer excited him as much as they used to. He started going to shopping malls specifically for the purpose of looking at women and girls, whom he would later fantasize about raping while he masturbated. When he then began to feel compelled to study the patterns of the women who worked in the malls and to compile schedules of their comings and goings, he became scared that he was in danger of acting on his fantasies. At that point, he sought help.

Lori was an MBA graduate and a highly effective manager. Yet she was unable to hold a job for more than a year. When she began a new job, her performance was exemplary. After about 2 to 6 months, she would begin to act as though she were distracted and less engaged. The quality of her work would gradually decline, and her work relationships would become strained. Eventually, she would be asked to resign and would comply.

Lori was in love with being in love. She loved the boost to her self-esteem and self-confidence; the soft ongoing sexual arousal that made her feel fully alive; the sexual excitement that thrilled her when she just thought about her lover; and the “mind-blowing” orgasms she experienced during sex with him. Being in love filled her emptiness, made her whole, kept the pain and terror out of her awareness, and gave her a reason to live.

When Lori was in love with a man, nothing else in her life felt as important to her as having sex with him. She would want sex desperately. If circumstances prevented her from having sex with him, she would become restless, then agitated, then frantic. She could interrupt this sequence by masturbating during the restless stage before she became agitated. Otherwise, she could terminate such episodes only by drinking herself into a stupor. When she was in love, she gradually neglected everything else in her life, including her work. When she was not in love, she would search desperately for a man and typically would find someone with whom to fall in love and have sex. Often, her feeling of being in love did not last. Often, the man lost interest before she did.

On several occasions, Lori was reminded that her trouble with employment was related to her love life. When she was in love, each time she tried to hold back or defer sexual activity—for example, to complete a work assignment or attend a meeting—she experienced the aforementioned sequence of restlessness, agitation, and frenzied panic. When she was not in love and refrained from her desperate quest—primarily by staying home during evenings and weekends—she experienced abandonment feelings that intensified, threatened to overwhelm her, and were increasingly accompanied by suicidal thoughts. Twice she had attempted to kill herself.

After Lori's 30th birthday, she found herself increasingly drawn to "bad boys," men with an air of danger who did not follow rules. One evening, some friends of a boyfriend who had moved in with her joined them for dinner. An hour later, a dozen FBI agents stormed in and placed everyone under arrest. Two kilos of uncut cocaine were later found in Lori's house. Lori and her boyfriend were arrested for possession with intent to distribute and operating a continuing criminal enterprise.

Lori was allowed to plead guilty to a minor charge in exchange for her cooperation with prosecution. A year or so after the trial, she began to feel hints of the familiar craving to fall in love and be swept into a delicious maelstrom of sex and passion. She had by then come to realize that many of the misfortunes in her life had resulted from following where that craving led. When the hints became stronger, she sought help.

Wayne, a college dropout in his middle 40s, had difficulty holding a job despite being a capable computer programmer and a gifted musician. He had no close friends and spent much of his free time by himself, either working on his computer or playing his electric piano through headphones. Sometimes he would go to a casino, which he said that he did in order to be around other people.

Wayne had been involved in two brief relationships with women, both of whom he drove away by his demanding possessiveness and paranoid jealousy. He tended to develop obsessive crushes on women whom he hardly knew and then would feel driven to watch and follow them. Complaints of harassment by female coworkers had led to his being fired from two jobs, and once he was arrested for stalking.

Wayne masturbated several times a day, even at work. At night, he sometimes called random telephone numbers until he found a woman who would answer his questions about her sex life while he masturbated. When he had an urge to masturbate and did not act on it, he experienced a disorganizing panic that would intensify until he felt that he was about to burst. He found that he could not resist these urges, even when succumbing could jeopardize his job or get him into trouble with the law.

The strongest urge that Wayne experienced was to expose his penis to a woman and masturbate while she looked on in shock and fear. For this reason, he particularly liked to expose himself in elevators, when he and a woman were the only passengers. Even after two arrests, one conviction, and one occasion on which a woman’s boyfriend beat him severely, Wayne felt driven to continue riding elevators and hunting for unaccompanied women. One time, Wayne targeted a woman who had once been raped. Having vowed that she would never be victimized like that again, she carried a handgun. When Wayne turned toward her with his penis exposed, she panicked and shot him. He survived, thanks in part to the woman’s immediate 911 call. Six months after being discharged from the hospital, he was arrested again for exposing his penis to a woman in an elevator.

While the three persons who are described in the case examples differed in many respects, they had one trait in common. All engaged in some form of sexual behavior in a pattern that was characterized by two key features: recurrent failure to control the behavior and continuation of the behavior despite significant harmful consequences.

DIAGNOSIS AND RELATED MATTERS

Terminology

Agreement on the name of this disorder of driven sexual behavior is not universal. The primary contenders have been *sexual compulsivity* (or *compulsive sexual behavior*) and *sex addiction* (or *sexual addiction*). *Sexual compulsivity* is the name given to this condition by investigators who argue that the symptomatic sexual behavior is compulsive because it functions to reduce anxiety and other painful affects. While phenomenologic characteristics and treatment research support classification of this condition as an addictive disorder, the clearest argument against describing its symptomatic behavior as compulsive appears in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) and also in previous editions of the DSM. The definition of compulsion (compulsive behavior) in DSM-5-TR includes its function of providing relief from anxiety and other painful affects. However, it also specifies that compulsions are not performed to produce pleasure. Although reduction of anxiety or distress contributes to a person's motivation to engage in the sexual behavior that characterizes this disorder, pleasure or gratification also contributes. The relationship between compulsion and the condition being considered here is explicitly clarified in the differential diagnosis of OCD:

Other compulsive-like behaviors. Certain behaviors are sometimes described as “compulsive,” including sexual behavior (in the case of paraphilias), gambling (i.e., gambling disorder), and substance use (e.g., alcohol use disorder). However, these behaviors differ from the compulsions of OCD in that the person usually derives pleasure from the activity and may wish to resist it only because of its deleterious consequences. (Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, pp. 270, 271 [Copyright © 2022]. American Psychiatric Association. All Rights Reserved.)

A suitable name for the condition under discussion would designate behavior that, like compulsive behavior, (1) feels driven, (2) entails harmful or unpleasant consequences, and (3) functions to reduce anxiety or other painful affects; and also that—unlike compulsive behavior—(4) functions to produce pleasure or gratification. *Addiction* is the term that best fits this description. Drug addiction, for example, has the characteristics of feeling driven, entailing harmful consequences, and functioning both to relieve painful affects and to produce pleasure.

However, determination of whether “sex addiction” is the most appropriate designation for the condition of driven sexual behavior that is being considered here requires a clear and meaningful definition of addiction.

Definition of Addiction

As noted in DSM-5-TR, neither tolerance nor withdrawal is necessary nor are both together sufficient for a diagnosis of substance use disorder. The characteristics that seem to be both necessary and sufficient for identifying a pattern of psychoactive substance use as a substance use disorder are (1) recurrent failure to control the use of one or more psychoactive substances and (2) continuation of psychoactive substance use despite significant harmful consequences. (“Recurrent failure to control” does not mean that addicted individuals invariably lose control when they use drugs. It means that their predictions that they would refrain from or limit their drug use have repeatedly proven to be unreliable.)

The preceding discussion of terminology identified two critical characteristics of addictive behavior. It can reduce anxiety and other painful affects, as does compulsive behavior. In addition, it produces pleasure or gratification (that may diminish with repetition). Combining this distinctive dual motivational function—positive as well as negative reinforcement—with the key features that distinguish drug addiction from simple drug use yields a workable, behaviorally nonspecific definition of addiction, as follows. *Addiction* is a condition in which a behavior that can function both to produce pleasure and to reduce anxiety or other painful affects is employed in a pattern that is characterized by two key features: (1) recurrent failure to control the behavior and (2) continuation of the behavior despite significant harmful consequences.

The definition of a specific addictive disorder can be derived from the definition of addiction by replacing the phrase, “a behavior that can function both to produce pleasure and to reduce painful affects” with the name of a behavior that can perform both of these functions (e.g., alcohol consumption, gambling, eating, sexual behavior). Accordingly, sex addiction is defined as a condition in which some form of sexual behavior is employed in a pattern that is characterized by two key features: (1) recurrent failure to control the behavior and (2) continuation of the behavior despite significant harmful consequences. In other words, sex addiction is a condition in which some form of sexual behavior relates to and affects a person’s life in such a manner as to accord with the definition of addiction. A sex addict is a person who engages in some form of sexual behavior addictively—that is, in a pattern that is characterized by recurrent failure to control and continuation despite significant harmful consequences.

In a reprise of terminology matters, the definition of addiction as a pattern of behavior indicates that addiction is accurately identified not as something that a person has, like cancer, but as something that a person does. Also inaccurate is the characterization of a person as addicted to a substance or behavior, which would imply that the person is a passive victim over whom the substance or behavior has control. The engine of addiction is not in a substance or behavior. It is in the person. The link between a person and an addictive disorder or pattern of behavior is most accurately described by a statement to the effect that a person engages in one or more behaviors addictively. Some common phrases such as “addicted to porn” are inaccurate not only for the reasons just mentioned but additionally because they misidentify the pathognomonic behavior. In an addictive disorder that involves pornography, the behavior that is used addictively is not the viewing of pornography. It is masturbation, for which looking at pornography serves as a facilitator or enhancer. Terminology was considered worthy of further discussion because imprecise use of “addiction” and related terms is sometimes exploited as an opportunity to discredit the term, however much the imprecision resides not in the term but in its user.

Diagnostic Criteria for Sex Addiction

DSM-5-TR excludes several behavioral addictions, including sex addiction, on grounds that peer-reviewed evidence is insufficient to establish their diagnostic criteria. Meanwhile, the generation of peer-reviewed evidence depends on investigators of this disorder having a valid and reliable set of provisional diagnostic criteria by which to identify subjects who are appropriate for their studies.

Provisional diagnostic criteria for sex addiction that follow the DSM format can be derived from the DSM-5-TR criteria for any substance use disorder, the paradigmatic addictive disorder, by replacing the name of the substance and its use—for example, *alcohol* and *alcohol use*—with the term *sexual behavior*, replacing *taken* with *engaged in*, and replacing “a characteristic withdrawal syndrome for the substance” with “a characteristic biopsychological withdrawal syndrome of physiologically and/or psychologically described changes upon discontinuation of the sexual behavior.” The set of criteria that is presented here demonstrates that diagnostic criteria for sex addiction can be developed that is consistent with the form and content of the current DSM, are expressed in the same descriptive language, and are likely to be as reliable and valid as are the DSM-5-TR diagnostic criteria for substance use disorder. To increase specificity and reliability, a diagnosis of sex addiction requires that at least four of the diagnostic criteria be met. (A diagnosis of substance use disorder requires only that two criteria be met.)

Sex Addiction

A maladaptive pattern of sexual behavior that has led to *clinically significant impairment or distress*, as manifested by the occurrence within a 12-month period of four (or more) of the following:

1. the sexual behavior is often engaged in over a longer period, in greater quantity, or at a higher level of intensity than was intended
2. efforts to cut down or control sexual behavior have repeatedly been unsuccessful
3. a great deal of time is spent in activities necessary to prepare for the sexual behavior, engage in the behavior, or recover from its effects
4. the subject experiences a craving (strong desire or urge) to engage in the sexual behavior
5. engaging in sexual behavior has resulted in failure to fulfill significant responsibilities at work, school, or home
6. important social, occupational, or recreational activities are given up or reduced as a result of engaging in the sexual behavior
7. the sexual behavior continues despite persistent or recurrent social or interpersonal problems that its effects have caused or exacerbated
8. the sexual behavior continues despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the behavior
9. the sexual behavior is recurrently performed in situations in which doing so is physically hazardous
10. tolerance, as defined by either of the following:
    a. producing the same levels of desired effects as on earlier occasions requires a frequency or intensity of sexual behavior that is markedly greater than had been required in the past

   b. engaging in sexual behavior at the same frequency and intensity as on earlier occasions produces levels of desired effects that are markedly lower than had been produced in the past
11. withdrawal, as manifested by either of the following:
   a. a characteristic biopsychological withdrawal syndrome of physiologically and/or psychologically described changes upon discontinuation of the sexual behavior
   b. the same (or a closely related) sexual behavior is engaged in to relieve or avoid withdrawal symptoms

These diagnostic criteria are far from the final word on diagnosing sex addiction. They are provisional and are likely to need revision in the light of further developments in research or theory. For example, investigators might find that the number of criteria required (four) is too low or that the required time frame (12 months) is unnecessarily long. They might determine that adding (or substituting) items from the DSM-5-TR diagnostic criteria for gambling disorder—such as preoccupation, engaging in the behavior to relieve dysphoric moods, restlessness or irritability when attempting to decrease or discontinue the behavior, or lying to conceal the extent of the behavior—enhances their discriminative utility. At the very least, these criteria provide a starting point for research. The research function of diagnostic criteria is critically important, particularly for newly recognized conditions. The inclusion of a condition in the next DSM depends on scientific research that documents its legitimacy. Meanwhile, a condition can be researched only if clear, valid, and reliable diagnostic criteria enable researchers to recognize it. Multiple varied sets of diagnostic criteria limit the generalizability of research results as well as undermine claims that the condition is a valid diagnostic entity.

Significantly, no form of sexual behavior in itself constitutes sex addiction. Whether a pattern of sexual behavior qualifies as sex addiction is determined not by the type of behavior, its object, its frequency, or its social acceptability, but by how the behavior relates to and affects a person's life. Any sexual behavior has the potential to be engaged in addictively but constitutes an addictive disorder only to the extent that it occurs in a pattern that meets the diagnostic criteria or accords with the definition. The key features that distinguish sex addiction from other patterns of sexual behavior are: (1) the person is not reliably able to control the sexual behavior and (2) the sexual behavior has significant harmful consequences and continues nonetheless.

Sex addiction can now be distinguished from the diagnostic entity in DSM-5-TR that is most similar to it, paraphilic disorder. DSM-5-TR defines *paraphilia* as “any intense and persistent sexual interest other than sexual interest [sic] in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners.” It defines *paraphilic disorder* as “a paraphilia that is currently causing distress or impairment to the individual or a paraphilia whose [sic] satisfaction has entailed personal harm or risk of harm to others.” The most apparent distinction is that sex addiction can be diagnosed when its diagnostic criteria are met whether the symptomatic behavior is paraphilic or nonparaphilic, while paraphilic disorder is limited to paraphilias. A second distinction is that impaired ability to control the symptomatic behavior is prominent in the diagnosis of sex addiction but is mentioned in neither the definition of paraphilic disorder nor the diagnostic criteria for any of the paraphilic disorders. Third, risk of harm to others as a result of symptomatic behavior is sufficient to warrant a diagnosis of paraphilic disorder but not a diagnosis of sex addiction. Fourth, DSM-5-TR defines paraphilia as an interest, not a behavior. Diagnostic criterion B for most of the paraphilic disorders is “The individual has acted on these sexual urges with a nonconsenting person, *or the sexual urges or fantasies* (author’s italics) cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.” The definition of and diagnostic criteria for sex addiction depend on objectively observable events: sexual behavior, comparison between addicts’ predictions that they would refrain from or limit their sexual behavior and their subsequent sexual behavior, and consequences of the sexual behavior. Sexual interests, urges, or fantasies per se are not relevant to a diagnosis of sex addiction.

Clinical Examples. A few clinical examples are presented to illustrate the considerations that are involved in making a diagnosis of sex addiction.

Dale, a dealer of fine art, began psychoanalysis to help him get past his lifelong depression and inability to sustain an intimate relationship. Ever since he quit drinking 6 years earlier, he had been desperately lonely. Consciously he wanted nothing more than to find a partner, someone with whom he could share his life. However, he was very anxious in social interactions. He feared that he would not be able to hold up his end of a conversation and would then be humiliated. He avoided situations in which conversation was likely. Instead, he would go to parks or adult theaters where he could meet other men for anonymous sex. After these sexual encounters, he felt dirty and disgusted with himself. Often, he would suspect that he had picked up HIV. He also had been beaten several times and robbed twice. But when he was alone or even when he anticipated being alone—for example, when he was driving home after work or after an evening activity—he would experience intense anxiety that felt like he was coming apart into a billion pieces. He could not tolerate this feeling, and sexual activity relieved it. Masturbating to pornography at home took the edge off his anxiety and usually enabled him to sleep. However, he increasingly was finding that it did not help as much as it once had done. On numerous occasions, he tried to get involved in cultural or religious activities where he would be likely to meet educated, stable gay men. Every time he soon found himself back at a park or a theater.

Steve was a software developer in his 40s who was in treatment for depression, anxiety, and marital difficulties. Sex was among the sources of tension in his marriage. He wanted to have sex with his wife every day, sometimes two or even three times a day, and he became upset when she did not comply. When his wife declined to have sex with him, he felt desperate. He feared that she did not love him, that he was not good enough for her, and that she was tired of him and was preparing to leave him. On such occasions, he usually withdrew and immersed himself in work. He rarely masturbated, and he did not seek sex elsewhere. When his wife's lupus flared up, Steve cared for her sensitively, and she expressed appreciation and gratitude. At such times, he felt needed and valued, and he rarely thought of sex. Steve's desire for sex occasionally offended his wife, who felt then that he would rather have sex than talk with her. Sometimes when she complied with Steve's requests for sex, she resented him. Further inquiry did not reveal other harmful consequences from Steve's sexual behavior, nor did it suggest that he had any difficulty controlling his sexual behavior.

Jolene was a married emergency department nurse in her early 30s who was “in love” with two married men with whom she was sexually involved and having extramarital affairs. Meanwhile, she loved her husband Ed, and could not stand the thought of leaving him. She trusted him and felt that he understood her. He knew of Jolene’s recurrent pattern of intense infatuation with a new man, resisting, giving in to overpowering sexual attraction, and then becoming bored. When she was not sexually involved with at least one man outside her marriage she felt desperate, panicky, and empty. Typically, she would begin a new involvement as soon as she sensed that she was beginning to become bored with her current extramarital affair. Sure, she noted, she had tried to rein it in, many times. After all, she continued, it had cost her two marriages, her kids, her place in medical school, a whole lot of time, and a whole lot more emotional hell. She had tried meditation, counseling, and women’s support groups. She had joined a fundamentalist church. She even had taken excessive doses of medroxyprogesterone to decrease her sex drive until she developed a pulmonary embolus, from which she almost died. Jolene had become involved with Ed while she still was married to her second husband. She lived in constant fear that Ed, too, would get fed up with her and throw her out. Now one of her lovers was talking about killing himself if Jolene did not marry him. The other lover was talking about confronting Ed. Jolene felt overwhelmed and had developed symptoms of major depression and panic disorder.

Charla, a hairstylist and fashion model in her 20s, agreed to accompany her boyfriend Mike to a session with his psychotherapist. Mike was upset that Charla was having sex with other men and thought she might be a sex addict. Charla said that she had told Mike shortly after they met that sex was part of her career, and if he did not think he could stand it, they should not get involved. Having sex with wealthy and powerful men advanced her success as a model, she explained, and brought her money and expensive gifts. She acknowledged that what she was doing was like prostitution, but it was clean and legal, and she was in charge. She stated that she certainly did not do it for the sex, which did nothing for her. She was not orgasmic with these men. She likened having sex to cutting hair. Her rewards were the finished product, a satisfied customer, and a nice tip. She also enjoyed her sense of control over these wealthy and powerful men. Charla stated that she had never engaged in more sexual behavior than she intended and never tried or wanted to decrease her sexual behavior. She also denied having experienced withdrawal symptoms or the desire to engage in substitute behavior when she was not sexually active. She recognized that her sexual behavior was bothering Mike, but she said that it was his problem. She was making ten times as much money as her father ever did and was not about to give that up because Mike’s fragile male ego could not deal with it. Mike acknowledged that she seemed to be in control of her sexual behavior and that he was not aware of any problems that resulted from her sexual behavior other than its effect on him.

The clinical example of Dale seems to meet all the criteria except 1. The example of Steve might meet criterion 3 but does not seem to meet any of the other criteria. The example of Jolene meets criteria 2, 3, 6, 8, and probably 11. Charla probably meets criterion 5. She might or might not meet criterion 6, depending on the importance (to her) of the activities with Mike that she gives up to have sex with other men. Accordingly, Dale and Jolene merit diagnoses of sex addiction according to the diagnostic criteria, while Steve and Charla do not. (The conclusion is not that Charla's behavior is acceptable nor that she is psychiatrically healthy, only that she does not merit a diagnosis of sex addiction.) An informal assessment based on the definition of sex addiction reaches the same conclusions. Dale and Jolene demonstrate patterns of sexual behavior characterized by recurrent failure to control and continuation despite significant harmful consequences, while Steve and Charla do not.

Differential Diagnosis

A number of other conditions can at first glance look like sex addiction. The hypersexual activity and paraphilic behaviors that often characterize sex addiction can occur also as manifestations of underlying brain pathology and occasionally are its earliest or most prominent symptoms. Paraphilic or hypersexual behavior can occur in the context of a seizure disorder, especially in association with temporal lobe epilepsy. More broadly, any disorder that is associated with impairment of cerebral functioning can weaken normal inhibitory controls and thereby allow the expression of sexual behaviors that ordinarily are suppressed. Disinhibited sexual behavior has been reported particularly in patients with frontal lobe lesions and in older adult patients with dementia. Hypersexual behavior can occur also as a side effect of medication, particularly antiparkinsonian agents. Finally, sexually aggressive behavior has been associated with elevated levels of testosterone. Distinguishing these conditions from sex addiction is usually facilitated by the presence of additional symptoms or circumstances that suggest the underlying organic disturbance, although altered sexual behavior may be the earliest manifestation in some cases of brain pathology. Clues that invite an organic evaluation include onset in middle age or later, regression from previously normal sexuality, excessive aggression, report of auras or seizure-like symptoms prior to or during the sexual behavior, and impaired perceptual or motor skills. The most useful instrument for determining whether a case of paraphilic or hypersexual behavior represents sex addiction is the set of diagnostic criteria for sex addiction. Patterns of paraphilic or hypersexual behavior that are not symptoms of sex addiction are generally characterized neither by a persistent desire to cut down or control the behavior nor by tolerance or biopsychological withdrawal symptoms on discontinuation of the behavior (usually affective discomfort, irritability, or restlessness). The diagnostic criteria for sex addiction are useful also in distinguishing sex addiction from nonaddictive patterns of exploitative or aggressive sexual behavior that can occur with antisocial personality disorder.

Obsessions and compulsions with sexual content can occur in OCD. Sexual obsessions were reported in 32% of OCD patients in a large study. However, the content of these obsessions consisted most often not of sexual fantasies but of fears of acting on sexual impulses or fears of being a pervert. Sexual fantasies are typical of sex addiction. As noted earlier, the symptoms of sex addiction differ from sexual obsessions and compulsions primarily in that the former is associated with sexual arousal and sexual pleasure, while the latter are typically accompanied not by sexual arousal but by anxiety.

A syndrome that meets the diagnostic criteria for sex addiction can occur in the context of other psychiatric disorders, including bipolar disorder, schizophrenia, personality disorders, and psychoactive substance use disorder. When the diagnostic criteria for both sex addiction and another psychiatric disorder are met, both diagnoses are warranted, regardless of whether sex addiction might be secondary to the other psychiatric disorder. The diagnosis of sex addiction is a descriptive designation of how a pattern of sexual behavior relates to and affects a person’s life. It does not presume anything about how the pattern of sexual behavior developed nor is it precluded by the presence of other conditions that may have influenced its development.

Epidemiology

Two early studies reported that 3% to 6% of the American population suffer from sexual addiction, and 5% meet diagnostic criteria for sexual compulsivity. Slightly higher percentages of sexually compulsive respondents were reported by Swedish studies of individuals who used the Internet for sexual purposes. A smaller Canadian study found that 5 of 40 community subjects (12.5%) were sex addicts. A more recent and larger Canadian study reported that 50 of 114 (43.9%) incarcerated sex offenders and 21 of 117 (17.9%) socioeconomically matched community males reached the addiction criterion in the sexual addiction screening test, which was used also in the study that reported a prevalence of 3% to 6%. The authors attributed the difference to the higher socioeconomic class of the subjects in the earlier study.

About 80% of individuals who use sexual behavior addictively are male. Gender differences in prevalence are greater for paraphilic than for nonparaphilic sex addictions. Within the nonparaphilic arena, males tend to focus more on physical sexual gratification and thus more often engage addictively in masturbation, use of prostitutes, and impersonal sex. Females tend to focus more on the emotional aspects of sexuality and thus more often engage addictively in romantic relationships. Sex addiction is usually a chronic disorder with remissions and exacerbations.

Addictive use of sexual behavior typically begins in the teens, peaks between the ages of 20 and 40, and then gradually declines. The “modal subject” in a cohort that responded to an advertisement for evaluation and treatment of sex addictions and compulsive sexual behaviors was characterized as a 34-year-old, white, married, Catholic college graduate earning a middle-class income.

Comorbidity and Familial Patterns

A review of comorbidity findings is prefaced by the observation that little research has actually been conducted specifically with individuals who use sexual behavior addictively. For a variety of reasons, most of the reviewed research studied paraphilic subjects and sex offenders. While the group of sex addicts overlaps with the group of sex offenders and more so with the group of paraphilic subjects, these groups are not identical.

Researchers have noted significant comorbidity among different forms of sex addiction: individuals who engage addictively in one form of sexual behavior are likely also to engage addictively in other forms of sexual behavior. High frequencies of comorbidity have been observed not only within the category of paraphilic sex addictions but also between paraphilic and nonparaphilic sex addictions. A variety of psychiatric disorders have been reported to be comorbid with sex addiction at a rate that is higher than their prevalence in the general population. The strongest trend that the research reveals is significant comorbidity of sex addiction with substance use disorder, gambling disorder, bulimia nervosa, and compulsive buying. Significant comorbidity between sex addiction and mood disorders, anxiety disorders, attention-deficit hyperactivity disorder (ADHD), and personality disorders also has been reported. The one family history study that has been published found a significantly increased prevalence of sex addiction and other addictive disorders (substance use disorder, eating disorders, and gambling disorder) in the parents of sex addict probands. More research is needed in the areas of sex addiction comorbidity and family history, particularly in light of the usefulness of such findings in understanding etiology and in formulating treatment plans.

Course of Illness

A recent search of PubMed found no publications that reported on the course of illness for sex addiction (or for sexual addiction, sexual compulsivity, compulsive sexual behavior, or paraphilia). In DSM-5-TR, the course of illness descriptions for the paraphilic disorders mention possibilities but provide no information.

That sex addiction shares the addictive process with other addictive disorders suggests that its course of illness may be similar to those of the others. Thus far, the preceding statement is but a hypothesis in search of empirical investigation.

THE ADDICTIVE PROCESS

Other disorders in addition to sex addiction and substance use disorders fit the definition of addiction and fulfill the diagnostic criteria for addictive disorder, including gambling disorder, binge eating disorder, bulimia nervosa, and kleptomania. In addition, they share a number of clinical and phenomenologic features that are characteristic of addiction: (1) characteristic course—the disorder typically begins in adolescence or early adulthood and follows a chronic course with remissions and exacerbations; (2) behavioral features—narrowing of behavioral repertoire, continuation of the behavior despite harmful consequences; (3) individuals' subjective experience of the condition—sense of craving, preoccupation, excitement during preparatory activity, mood-altering effects of the behavior, sense of loss of control; (4) progressive development of the condition—craving, loss of control, narrowing of behavioral repertoire, and harmfulness of consequences all tending to increase as the duration of the condition increases; (5) experience of tolerance—as the behavior is repeated, its potency to produce reinforcing effects tends to diminish; (6) experience of withdrawal phenomena—psychological or physical discomfort when the behavior is discontinued; (7) tendency to "relapse"—to return to harmful patterns of behavior after a period of abstinence or control has been achieved; (8) propensity for behavioral substitution—when the behavioral symptoms of the disorder have come under control, tendency for addictive engagement in other behaviors to emerge or intensify; (9) relationship between the condition and other aspects of affected individuals' lives—neglect of other areas of life as the behavior assumes priority; and (10) recurrent themes in the ways individuals with these conditions relate to others and to themselves—including low self-esteem, self-centeredness, denial, rationalization, and conflicts over dependency and control.

That these six conditions with diverse symptomatic behaviors—sex addiction, substance use disorders, gambling disorder, binge eating disorder, bulimia nervosa, and kleptomania—meet the same set of diagnostic criteria for addictive disorder and share such an array of clinical features suggested a hypothesis that they—and, by extension, addictive disorders in general—share an underlying biopsychological process. This hypothesis has been supported by extensive research findings that demonstrated (a) significantly elevated lifetime comorbidity among these conditions and between them and other psychiatric disorders, (b) significant family history relationships, (c) similar responses to psychiatric medications, (d) similar results on psychometric assessments, and (e) similar neurobiologic correlates. Comprehensive reviews have concluded that variation in the liability to a substance use disorder correlates with personality phenotypic variations that predate the initiation of substance use. Prospective studies have reported the temporal and predictive primacy of anxiety, mood, and ADHD when one of them is found to be comorbid with a substance use disorder. Subsequent studies found that deficits in affect- and self-regulatory functioning usually precede and increase the risk for development of substance use disorders, bulimia nervosa, gambling disorder, and sex addiction. That the documented abnormalities of psychological and neurobiologic functioning are temporally primary to and predictive of the behavioral syndromes that have been under consideration here suggests that the underlying biopsychological process that these conditions share precedes their onset and is not simply a consequence of the behavior or lifestyle that characterizes them.

Definition

Addictive process is the term that designates the core biopsychological process that addictive disorders are hypothesized to share. It develops prior to the emergence of addictive patterns of behavior and constitutes a biopsychological predisposition to develop an addictive disorder. It can be defined descriptively as an enduring, inordinately strong tendency to engage in some form of pleasure-producing behavior in a pattern that is characterized by impaired control and continuation despite harmful consequences. It is not what makes cocaine, ice cream, or sex pleasurable for people in general but what makes the drive for cocaine, ice cream, or sex so much more inexorable for those who use it addictively. The class of addictive disorders includes substance use disorders, gambling disorder, binge eating disorder, bulimia nervosa, kleptomania, sex addiction, and other enduring conditions in which a behavior that can function both to produce pleasure and to reduce painful affects is employed in a pattern that is characterized by two key features: (1) recurrent failure to control the behavior and (2) continuation of the behavior despite significant harmful consequences. The group of addictive disorders is most usefully considered as not a collection of distinct disorders but an underlying process that can be expressed in one or more of various behavioral manifestations.

Thus, the development of an addictive disorder is shaped by two sets of factors: those that contribute to the underlying addictive process and those that guide the selection of a particular behavior as the one preferred for addictive use. Whereas the type of behavior that is being used addictively is the most readily noticeable manifestation of an addictive disorder, the addictive process is the component of the disorder that leads to the behavior being used in ways that are pathologic. In other words, the addictive process is the underlying disease, and an instance of addictive behavior is a symptom of the disease. Addictive behavior is behavior that the person under consideration is using or is likely to use addictively: that is, with impaired control and despite harmful consequences.

That the addictive process is a biopsychological process does not mean that it represents an interaction between biologic and psychological, nor that it has psychological properties that emerge out of relationships within its biologic system. Biologic and psychological are not distinct forms of reality but discrete sets of terms that represent distinct ways of experiencing and understanding a unitary human reality. The addictive process is a unitary biopsychological process that can be described and understood in both biologic and psychological terms. Brief neurobiologic and psychological formulations of the addictive process follow.

Neurobiologic Formulation

From the neurobiologic standpoint, the underlying vulnerability that all addictive disorders share can be understood to involve impairments in three inter-related functional systems: motivation-reward, affect regulation, and behavioral inhibition.

Impaired motivation-reward exposes addicts to unsatisfied states of restless anhedonia, irritable tension, and subjective emptiness. In the context of impaired motivation-reward function, behaviors that are associated with activation of the reward system are more strongly reinforced (via both positive and negative reinforcement) than they otherwise would have been. Motivation-reward impairment may additionally distort the relative reward values among varieties of experiences.

Impaired affect regulation renders addicts chronically vulnerable to painful affects, affective hyper-responsivity, and emotional instability. In the context of impaired affect regulation, behaviors that are associated with escape from or avoidance of painful affects are more strongly reinforced (via negative reinforcement) than they otherwise would have been. Combined impairments of motivation-reward and affect regulation particularly enhance the salience of drug self-administration and other behaviors that are associated with both (a) activation of the reward system and (b) escape from or avoidance of painful affects.

Impaired behavioral inhibition increases the likelihood that urges for some form of reinforcement in the short term (negative, positive, or both) will override the consideration of longer-term consequences, both negative and positive. The combination of impaired motivation-reward, impaired affect regulation, and impaired behavioral inhibition produces a condition in which urges to engage in behaviors that both provide pleasure or gratification and reduce painful affects are extraordinarily difficult to resist despite the harmful consequences that they might entail.

Impairments in motivation-reward, affect regulation, and behavioral inhibition result from interactions among genetic and environmental influences. They can be characterized as vulnerability factors, biologic markers, or endophenotypic dimensions of addiction. The diathesis-stress model provides an etiologic schema that guides the organization of research findings. Genetic predispositions interact with adverse experiences during critical phases of development to result in a phenotype that is neurobiologically vulnerable to the effects of stress later in life. This phenotype thus lowers an individual's threshold for developing an addictive disorder upon further stress exposure. Factors that have been found to contribute to the development of an addictive process include genetics, maternal gestational (prenatal) stress, caregiving deficiencies during infancy, and adverse childhood events or conditions.

Genetics. Researchers now generally believe that the predisposition to develop an addictive disorder results from the interaction of multiple genes. A large number of genes contribute to the risk for substance use disorder, but no single gene displays such a large magnitude of effect that it accounts for a major fraction of the genetic influence. The same holds for gambling disorder. Meanwhile, most of the genetic liability to developing addictive use of any one psychoactive substance is shared among the substances, as distinct from liability that is specific to a particular substance or class of substances. Along similar lines, the genetic risk for alcohol use disorder accounts for much of the risk for gambling disorder, and genes that increase the risk of developing gambling disorder increase the risk of developing other impulsive-compulsive and addictive patterns of behavior. Many addiction-related genetic variants (polymorphisms) do not fit into categories that are defined by substances or behaviors and are more usefully organized into categories that are defined by the brain functions that they alter. One such set of categories is motivation-reward, affect regulation, and behavioral inhibition.

MOTIVATION-REWARD. The homozygous *11* genotype of the dopamine (DA) D_1 receptor is associated with increased risk of alcohol use, cigarette smoking, use of other drugs, gambling, compulsive shopping, and compulsive eating. The Taq *A1* allele of the D_2 receptor gene predicts alcoholism, cigarette smoking, addictive use of psychoactive substances, pathologic gambling, and exaggerated reward value of food. The Taq *A1* allele is associated with reduced D_2 receptor density, hypersensitive presynaptic D_2 receptors, and decreased general responsiveness of the reward system to rewarding stimuli, along with heightened responsiveness after events that increase levels of DA in the synapse between the ventral tegmental area and the ventral striatum. Such an increased reward effect against a baseline of diminished reward could promote the development of an addictive disorder by intensifying a person's motivation to repeat behaviors that increase intrasynaptic DA in the midbrain motivation-reward system. Behaviors that do so include self-administration of a hedonic substance, eating (especially sweets), gambling, and engaging in sexual behavior. The Val(158) allele of the COMT gene that codes for catechol-*O*-methyl transferase (an enzyme that inactivates DA and norepinephrine [NE]) is associated with alcoholism, methamphetamine abuse, heroin addiction, and polysubstance abuse.

Variants of the gene that codes for the κ-opioid ligand prodynorphin occur more frequently in alcoholics, cocaine abusers, and methamphetamine addicts than in controls. Polymorphisms of the gene for the cannabinoid CB_1 receptor are associated with increased risk for addiction to alcohol, cocaine, amphetamines, cannabis, and multiple substances.

AFFECT REGULATION. The gene that encodes the serotonin (5-HT) transporter protein has a variant site (*5-HTTLPR,* for 5-HT transporter-linked polymorphic region) that is characterized by 2 alleles, 1 short (*s*) and the other long (*l*). The *s* allele, and especially the homozygous *s*/*s* genotype, is associated with alcoholism, heroin addiction, cigarette smoking, pathologic gambling, bulimia, and binge eating disorder. It is associated also with affective instability, anxiety-related personality traits, and heightened sensitivity to mild stressors.

The *A* allele of the gene that encodes brain-derived neurotrophic factor (BDNF) is associated with alcoholism, methamphetamine abuse, heroin abuse, tobacco smoking, and all subtypes of eating disorders. It is specifically associated with binge eating behavior, a phenotypic trait that occurs in both bulimia and binge-eating disorder. The long allele of another BDNF gene variant, in the gene's promoter region, is associated with vulnerability to polysubstance use disorder.

Alcoholism is associated with three polymorphisms of the gene that codes for neuropeptide Y (NPY) and with two haplotypes of the galanin gene. The mediating link in both cases is thought to be impaired regulation of anxiety.

BEHAVIORAL INHIBITION. Whereas DA D_1, D_2, and D_3 receptors play central roles in the motivation-reward system, D_4 and D_5 receptors are involved primarily in behavioral inhibition and attentional processing. The long allele of a polymorphism in the D_4 receptor gene is associated with impulsive personality traits and is a risk factor for adolescent alcohol abuse, adolescent "hard drug" use, heroin abuse, cue-elicited heroin craving, greater severity of alcohol and opiate addiction, pathologic gambling, binge eating, and cue-elicited craving for food.

The common 148 bp variant of the D_5 receptor gene is correlated with substance abuse and also with ADHD and novelty seeking. By itself, the 10-repeat allele of the DA transporter (DAT) gene *DAT1* is not associated with increased consumption of alcohol. However, the correlation between novelty seeking and increased alcohol consumption is significantly greater with this allele than with the normal genotype.

Studies have reported associations between variants of the gene *GABRA2*, which encodes the α-2 subunit of the $GABA_A$ receptor, and both alcoholism and polysubstance use disorder. Risk alleles of this gene are associated also with conduct disorder in children and with antisocial personality disorder in adults. Polymorphisms of the gene that encodes the α-3 subunit of the $GABA_A$ receptor are associated with alcoholism.

Although impaired behavioral inhibition or impulsivity is a key feature of addiction, research has linked variants of genes that code for 5-HT_{1B} and 5-HT_{2A} receptors with greater impulsivity among alcoholics and bulimics, respectively, but not with increased risk for any addictive disorder. In at least some instances, genotypic variations seem to map onto disorder-relevant intermediate phenotypes (i.e., trait-level variations) within a population that is affected by a particular disorder more closely than they map onto gross phenotypes, such as the disorders themselves.

Maternal Gestational (prenatal) Stress. Research with rodents and monkeys has indicated that maternal gestational stress (MGS) amplifies the subsequent reinforcing effects of ethanol, psychostimulants, and morphine on the offspring. It accelerates sensitization to amphetamine, increases motor-responsiveness to cocaine, and potentiates cocaine-primed reinstatement of cocaine-seeking behavior. In addition, it intensifies physiologic-emotional responses to postnatal stress, retards the learning of both active and passive means of managing stress, and increases impulsivity. Prospective studies with human subjects have found MGS to be associated with high affective/behavioral reactivity, negative affect, difficulty being consoled, and disinhibitory traits in the offspring. The consensus among investigators is that exposure to MGS results in a general susceptibility to psychopathology rather than increased risk for any particular form of psychopathology.

Caregiving Deficiencies During Infancy. Considerable development of the human central nervous system occurs after birth, particularly during the first 2 years of life. Postnatal brain development is highly responsive to conditions in the environment. Epidemiologic, clinical, and preclinical data indicate that early exposure to adverse environments engenders a vulnerability to distortion of the physiologic stress response and subsequent impairments in affect regulation, motivation-reward, and behavioral inhibition. With respect to postnatal brain development in mammals, the most important constituent of the environment is the mother (or mother-substitute). Research has investigated the potential consequences in adulthood of two mother-related variables that may occur during infancy: maternal separation (MS) or deprivation and deficiencies in the quality of maternal care.

MATERNAL SEPARATION. Compared to normally reared rats, adult rats that were exposed to MS during infancy are characterized by increased ethanol and sucrose consumption; amplified sensitivity to the neurochemical and behavioral effects of psychostimulants and opiates; increased susceptibility to the rewarding properties of psychostimulants, opiates, and food; enhanced acquisition and maintenance of operant responding for drug or food reinforcer; elevated risk of developing addiction-like patterns of consuming or self-administering ethanol, cocaine, morphine, and sucrose solution; and greater tendency to overeat and gain weight when given free access to food. On a fasting/refeeding schedule, compensatory hyperphagia during refeeding days diminishes gradually in rats that were raised normally but continues in MS rats. A prospective study with human subjects found that compared to offspring who had been breastfed for more than 1 month, offspring who had been weaned at age 1 month or earlier had a 1.47-fold greater risk of being hospitalized in a psychiatric unit with an ethanol-related diagnosis.

MS during infancy is associated also with other behavioral abnormalities. Most common are behaviors that suggest impaired affect regulation: increased anxiety-like behaviors in response to aversive environmental stimuli, intensified behavioral and visceral reactivity to stress, increased startle response, increased fearfulness in the face of novelty, increased depression-like behavior, decreased social interaction, reduced coping behavior in stressful environments, and increased vulnerability to developing anxiety-like or depression-like behavior when subsequently exposed to chronic stress. The amount of ethanol consumed by MS animals is highly correlated with the magnitude of the glucocorticoid (GC) response to a mild stressor and with measures of anxiety-like and fearful behaviors in both rats and monkeys.

Behaviors that are consistent with impaired motivation-reward function have been reported in MS research with rats and with monkeys. These include reduced social motivation, blunted perception of differences in reward value, and reduced operant responses on progressive ratio reinforcement schedules, which suggest either low motivation or diminished sensitivity to reward. MS rats' low motivation and diminished sensitivity to reward have been normalized by administration of fluoxetine.

Other studies of MS animals found increased impulsive behavior, locomotor hyperactivity, reduced prepulse inhibition of the startle response, deficits in shifting the attentional set, lower-risk assessment and higher-risk taking, and impaired retention of inhibitory avoidance. Children who were adopted from deprived institutional settings before age 43 months were found to display high degrees of inattention and overactivity at 6 and 11 years of age. They were found also to demonstrate deficits in executive functions of planning, inhibition, set-shifting, working memory, generativity, and action monitoring, which were most severe in children who had experienced more than 6 months of institutional maternal deprivation.

MATERNAL CARE DEFICIENCIES. A group of studies has explored the relationship between naturally occurring variations in maternal care of infant rats and the latter's capacity for affect regulation as they develop into adulthood. Maternal care is represented by mother rats' licking or grooming and arched-back nursing (LG-ABN) of their newborn progeny—simply licking and grooming (LG) in some recent studies. These studies have provided a credible experimental model for the relationship between the maternal care of human infants and their ensuing development.

Differences in the frequency of these maternal care behaviors have been found to be predictive of individual differences in affect regulation in the offspring when they become adults. Compared to the offspring of mother rats that show high levels of LG-ABN, the offspring of low–LG-ABN dams exhibit heightened anxiety-like behavior, exaggerated responses to stress, and less time spent in social interaction. Female offspring of low–LG-ABN mothers exhibit earlier puberty, increased sexual receptivity, and greater vulnerability to stress-induced binge-eating than do their high–LG-ABN counterparts.

To test the hypothesis that the observed characteristics of low–LG-ABN mothers' offspring had resulted from lower levels of maternal care, as distinct from genetic factors that also produce low–LG-ABN behavior, rat pups were "cross-fostered"—raised from birth by mothers whose LG-ABN frequency was opposite from that of the mothers to whom they were born. Pups that were born to high–LG-ABN dams and raised by low–LG-ABN mothers become hyperemotional, high-strung adult rats. Meanwhile, pups that were born to low–LG-ABN dams and raised from birth by high–LG-ABN mothers become mellow, well-adjusted adult rats. These findings support the hypothesis that the lower levels of maternal care that these rats received during their early postnatal lives was a critical determinant of the observed differences in adult rat functioning.

Variations in maternal licking/grooming influence the development of stress-responsiveness primarily through central processes that stimulate—via amygdalar corticotropin-releasing hormone (CRH)—or inhibit—via gamma-aminobutyric acid (GABA)—the noradrenergic systems that activate endocrine and behavioral responses to stress. Relative to offspring of high–LG-ABN mothers, adult offspring of low–LG-ABN mothers exhibit increased CRH expression in the central amygdala (CeA), increased CRH receptor density in the locus ceruleus (LC, primary site of NE synthesis), decreased density of hippocampal GC receptors (and hence diminished GC feedback sensitivity), decreased expression of glutamic acid decarboxylase (the rate-limiting enzyme in GABA synthesis) in the medial prefrontal cortex (PFC), reduced GABA affinity of benzodiazepine (BZD)-$GABA_A$ receptor complexes in the LC and nucleus tractus solitarii, and decreased BZD-$GABA_A$ receptor complex densities in the basolateral amygdala, CeA, and LC. Consequently, the offspring of low-LG-ABN mothers display higher stress–induced increases in paraventricular nucleus levels of NE than do the offspring of high–LG-ABN mothers. Noradrenergic input to the paraventricular nucleus provides the primary source of activation for synthesis and release of the CRH that initiates that hypothalamic–pituitary–adrenal (HPA) axis cascade. Compared to adult offspring of high–LG-ABN mothers, adult offspring of low–LG-ABN mothers also show decreased mGluR1 mRNA and protein in the hippocampus, decreased type I metabotropic glutamate receptor (mGluR1)-induced hippocampal long-term depression, and increased paired-pulse depression (PPD). PPD is an inhibitory feedback process that prevents excessive glutamate release during high-frequency stimulation.

At the heart of these differences in neurotransmitter/neuromodulator and receptor functioning are differences in gene expression. Maternal care of infants regulates the expression of the hippocampal glucocorticoid receptor (GR) gene by influencing two processes: acetylation of histones H3-K9 and methylation of the NGFI-A consensus sequence on the exon 1(7) promoter. Adult offspring of low–LG-ABN mothers were found to have lower levels of DNA methylation than do adult offspring of high–LG-ABN mothers. These differences emerged over the first week of life, were reversed with cross-fostering, persisted into adulthood, and were associated with altered histone acetylation and transcription factor (NGFI-A) binding to the GR promoter.

Central infusion of either a histone deacetylase inhibitor or a methyl donor removed the group differences in NGFI-A binding, GR expression, and HPA and behavioral responses to stress. These findings suggest a causal relation among epigenomic state (the sum of all epigenetic changes [DNA methylations and histone modifications] to an organism’s genome), GR expression, and the effect of maternal-infant care on subsequent stress responses in the offspring. Moreover, they demonstrate that an epigenomic state of a gene can be established through behavioral programming and is potentially reversible.

The demonstration by this body of studies that naturally occurring differences in maternal care of infants are correlated with subsequent differences in the behavior and neurobiology of adults constitutes an important evidence-based bridge between neuroscience and psychodynamic/psychoanalytic understanding.

Adverse Childhood Events or Conditions. Children who have been sexually or physically abused manifest abnormal baseline and stressor-responsive cortisol levels, either abnormally elevated or abnormally flat. Childhood abuse may sensitize the stress response system, thus rendering persons who were abused during childhood particularly vulnerable to stress and increasing their risk for stress-related disorders. This vulnerability may result in hypersecretion of CRH when these individuals are stressed.

Upon exposure to a standardized (laboratory) psychosocial stressor, women with a history of childhood sexual or physical abuse demonstrated markedly increased pituitary–adrenal and autonomic responses. The mean adrenocorticotropic hormone response was highest in women with a history of childhood abuse and current major depression, who also showed significantly increased cortisol responses to psychosocial stress. These findings suggest that HPA axis hyper-reactivity, probably due to hypersecretion of CRH, is a persistent consequence of childhood abuse that may contribute to a diathesis for later development of addiction and other psychiatric disorders.

A study screened 120 healthy college students for quality of parental care during childhood. Five from the top end of the distribution and five from the bottom end were invited to participate in a PET study during which they were asked to complete a stressful psychosocial task. The scans indicated that the psychosocial stressor elicited a significant release of DA in the ventral striatum of subjects in the low but not the high parental care group. The low parental care group also showed higher baseline cortisol levels and higher increases in cortisol during the stressful task. The magnitude of the cortisol response to stress was highly correlated with the magnitude of the ventral striatum DA response. These findings suggest that the chronic stress of neglectful or abusive parental care during childhood results in an HPA axis that is hypersensitive to psychosocial stressors and a midbrain that is hyper-responsive to triggers of DA release—conditions that are highly conducive to the development of addictive disorders.

In preclinical studies, reinstatement of drug-seeking behavior after extinction of its association with drug delivery can be elicited by brief exposure to a stressor. In human subjects, exposure to stressors and presentation of stress-related imagery have been identified as potent triggers for drug-seeking and recurrence of drug use. Most studies on drug self-administration have reported increases in responding after repeated or prolonged exposure to stress levels of GCs. GCs are understood to enhance drug responding by selectively facilitating DA transmission in the nucleus accumbens shell. During chronic stress, repeated increases in GCs and DA result in sensitization of the reward system. This sensitized state, which can persist after the end of the stress response, renders subjects more responsive to pleasurable substances or behaviors that are associated with release of mesolimbic DA and consequently more vulnerable to the development of addiction.

Thus, addicts' vulnerability to stress-induced reinstatement of drug-seeking and thence to drug use depends on the sensitivity of their HPA axis and the responsiveness of their mesolimbic dopaminergic system, in addition to the frequency and intensity of stressor exposures. Both elevated baseline cortisol levels and higher increases of cortisol in response to stressors are common sequelae of adverse conditions or recurrent adverse events during childhood.

Stress and disorders that are related to chronic stress tend to increase dendritic atrophy, accelerate neuronal degeneration, and subvert neuronal regeneration in the hippocampus and PFC. Mediating factors may include chronically elevated levels of GC, decreased expression of BDNF, stunted sprouting of serotonergic axons from insufficient availability of BDNF, glial cell loss, and decreased arborization and density of noradrenergic axons. In the developing brain, elevated levels of catecholamines and cortisol may lead to structural deviations or deficits through accelerated loss of neurons, delays in myelination, abnormalities in developmentally appropriate synaptic pruning, and inhibition of neurogenesis. Sustained GC exposure truncates dendrites and impairs neurogenesis in the hippocampus and PFC. Reduced baseline and hyporesponsive cortisol levels also can cause neuronal damage.

Together, these processes feed the downward spiral by potentiating hippocampal and cortical atrophy. Neuronal degeneration in the hippocampus and PFC diminishes the capacity of these regions to modulate or inhibit amygdalar stress/fear pathways and undermines hippocampal inhibitory control over cortisol release by the HPA system. Evidence of neuronal loss in the anterior cingulate cortex (ACC) has been reported in children, adolescents, and nonhuman primates with histories of adverse experiences early in life. In addition, adult survivors of early abuse have been found to have changes in hippocampal structure and function. Thus, these stress-induced processes may lead to compromised executive function, impaired affect regulation, and a greater incidence of impulsive behaviors.

Psychological Formulation

The central component of the addictive process as psychologically formulated is impaired self-regulation. Associated character pathology emerges from the same genetic-environmental matrix in which the self-regulatory impairments originate and develop in response to the interactive effects of impaired self-regulation and adverse personal history.

Impaired Self-Regulation. The descriptive definition of the addictive process that was presented earlier identifies objectively confirmable features that observers of the person in question might similarly apprehend. The addictive process also has a subjective definition; that is, what it feels like from the inside. Defined subjectively, the addictive process is an enduring tendency to feel driven to use some form of pleasure-producing behavior as a consciously or unconsciously intended means of relieving or avoiding painful affects and regulating one’s sense of self. A driven need to relieve painful affects and to regulate one’s sense of self suggests that addicts’ inherent systems for regulating affects and sense of self are impaired. Dependence on externally directed behavior to relieve painful affects and regulate one’s sense of self suggests a relative incapacity to utilize other, more adaptive means of managing. The subjective definition of the addictive process suggests that impaired self-regulation is at the nucleus of the addictive process.

Self-regulation is a comprehensive term for the biopsychological processes that regulate one's subjective states and behavior. The subjective states that are most affected when self-regulation is impaired are affects and sense of self. Volition, sensory experience, and thought processes are often also affected but less dramatically. Impaired internal regulation of people's subjective states leads them to depend on externally directed actions to regulate their affects and sense of self. Under such circumstances, intense and potentially traumatic affects may be experienced not as emotions but as urges to act. Impaired behavioral regulation limits people's capacity to resist urges to engage in actions that modify their affects or sense of self and that seem to promise, however illusorily, to protect them from emotional trauma.

The self-regulation system is a set of processes that are interrelated both functionally and developmentally. It can be understood to consist of three groups of functions: affect regulation, self-care, and self-governance.

Affect regulation functions are the psychobiologic processes that regulate the subjective, physiologic, behavioral, and interpersonal aspects of one's emotional states. These functions include self-soothing, self-enlivening, keeping affects' intensity within a manageable range, maintaining a balance when affects conflict, and tolerating affects without being overwhelmed.

Self-care functions concern the organization and regulation of one's perceptual, cognitive, executive, and behavioral processes in the service of self-protection and self-nurturing. Self-protection involves recognizing, assessing, warning oneself of, and defending oneself against dangers. Self-nurturing involves recognizing, assessing, setting priorities among, and taking care of one's needs. A critical component of self-care is the ability to use affects as signals or guides for appropriate action.

Self-governance functions include values, standards, self-esteem, self-punishment, and maintenance of a stable and cohesive sense of self. Self-governance thus subsumes (1) what psychoanalytic theory identifies as the superego—in its encouraging, approving, and rewarding aspects as well as its prohibiting, condemning, and punishing aspects; (2) the ego ideal or self-ideal, a fantasied representation of oneself that embodies all one's ideals; and (3) the processes that are involved in regulating one's sense of self.

The core self-regulation system develops during the first years of life out of the reciprocal interactions between the expression of infants' genes and infants' relationships with their primary caregivers. Considerable development of the human brain occurs after birth, particularly during the first 2 years of life, and its postnatal development is highly responsive to conditions in the caregiving environment. In healthy development, "good enough" genetic endowment interacts with caregivers' more or less adequate provision of functions that regulate the infants' somato-affective inner world. As their physiologies and prepsychological anlagen are challenged but not overwhelmed, infants gradually become able to provide for themselves the regulatory functions for the provision of which they had been depending on their caregivers. The metaphorical shorthand for this developmental process is *internalization*. However, various combinations of genetic and environmental factors can interfere with internalization and disrupt the development of the self-regulation system. Later in life, adaptive self-regulatory functioning, particularly in the areas of self-care and self-governance, depends on effective management of one's inner conflicts—which is predicated on awareness of them. When awareness of inner conflicts is blocked, their operation in the dark can distort the functioning of the self-regulation system—as can the processes that block such awareness.

To the extent that individuals' affect regulation is impaired, their emotional responses are easily provoked, unusually intense, and slow to recede. Their affect states tend to be unstable, intense, and disorganizing. Especially threatening are abandonment-separation anxiety, claustrophobic anxiety (anxiety associated with the general idea of being closed in, trapped, or smothered), depressive affects, the “superego affects” of guilt and shame, and affects that are associated with narcissistic injury. But almost any intense affect, including excitement or love, can be experienced as threatening when affect regulation is impaired.

To the extent that individuals’ self-care is impaired, they are deficient in their abilities to avoid danger, protect themselves, and take care of their needs. The dangers to which they expose themselves include physical, emotional, and narcissistic dangers. (“Narcissistic” means related to self-esteem and sense of self.) Similarly, the needs to which they do not adequately attend include physical, emotional, and narcissistic needs. As a result, they are particularly susceptible to getting hurt and being chronically dissatisfied on all three levels.

To the extent that individuals’ self-governance is impaired, they lack a consistent sense of self, a stable self-esteem, and a clear sense of direction. They may have skewed or fragmented values, ideals, and sense of meaning. Any threat to their sense of being in control can potentially trigger intense anxiety about being overwhelmed by helplessness. Their behavior tends to oscillate between extremes, and they may swing from actions that violate their values to actions that are self-injurious or invite punishment from the environment.

When individuals’ self-regulation is impaired, they live in a world of primitive pain, terrifying anxieties, and an unstable sense of self. They tend to respond with overwhelmingly intense affects to events that most others seem to take in stride. They experience the risk of being thus affectively overwhelmed and losing their self-coherence as threats to their survival, so they do what they can to avoid affective states that are potentially traumatic. Many seek desperately for something that can perform for them the self-regulatory functions that people with intact self-regulation systems are able to do autonomously. Often, they develop fantasies (usually unconscious) that the solution for their self-regulatory problems lies in something outside their selves: a substance, a person, a nonhuman object, a bodily state, or an institution. Many of them learn to ward off traumatic affects and self-states by engaging in a rewarding activity such as eating, taking a mood-altering substance into their bodies, gambling, or engaging in some form of sexual behavior. They then tend to become dependent on this activity to provide sham versions of self-regulatory functions that they have not been sufficiently able to provide for themselves.

When external or internal cues that are associated with intense affects or with loss of self-coherence become conditioned to particular craving sensations or discriminative stimuli for particular addictive-behavioral responses, these cues can trigger or be experienced as urges to engage in symptomatic behavior. Since these behaviors are addicts' desperate attempts to ward off traumatic affects and self-states that threaten their survival, their urges to enact the behavior typically are so imperative that their patterns of engaging in it are likely to be characterized by impaired control and by relative imperviousness to the restraining influence of harmful consequences.

Associated Character Pathology. *Character pathology* is an inclusive term that refers to both (a) enduring, pervasive, relatively inflexible patterns of inner experience and behavior that begin in adolescence or early adulthood and lead to significant functional impairment or subjective distress, and (b) the underlying psychobiologic processes of which the inner experience and behavior are observable manifestations (inner experience being observable to the subject). Its inclusion of (b) distinguishes it from the more widely used term *personality disorder*.

The character pathology that tends to be associated with addictive disorders originates under the same genetic and environmental circumstances as do the just discussed self-regulatory impairments. Its development is then shaped by infants' and children's needs to protect themselves from the overwhelming affects and loss of sense of self to which their personal history and impaired self-regulation expose them. Accompanying character pathology that tends to be associated with addiction (each to varying degrees in different individuals) includes: characteristic self-protective processes, impaired ability to symbolize affects, impaired management of the basic conflict, and reliance on the primal fantasy.

CHARACTERISTIC SELF-PROTECTIVE PROCESSES. The self-protective processes (often referred to as defenses) that people who engage addictively in one or more forms of behavior most typically employ are denial or disavowal, externalization, and the processes that constitute the narcissistic character/personality system.

Denial or disavowal is an unconsciously motivated failure either to recognize the reality of what is perceived or to appreciate the personal significance or implications of what is perceived. Its function is to support dissociation, an unconsciously intended removal from the realm of awareness something that if consciously experienced could precipitate overwhelming emotional pain or self-fragmentation. In addictive disorders, denial or disavowal most often occurs to support dissociation of: (1) painful affects, particularly guilt, shame, and affects that evoke guilt or shame; (2) one side or the other of an inner conflict, particularly the basic conflict and its derivatives; (3) narcissistic vulnerability and limitations; and (4) impulses that have been associated with severe trauma.

Externalization is an unconscious process whereby an aspect of one's self is experienced as an aspect not of oneself but of something external to oneself. It is the self-protective process that is most characteristic of addiction. The basis for people's transition from simply engaging in a rewarding activity to engaging in that activity addictively is their externalization of their self-regulatory functions to that rewarding activity or to the object of that activity. Their mental representations of their capacity to regulate their affects and sense of self shifts from their mental representations of their selves to their mental representations of that activity or object. In the course of this shift, their mental representations of their self-regulatory functioning are infiltrated by fantasies of omnipotence and become more effective in people's mental representations of the rewarding activities or objects than they ever could have been in real life.

The scope of externalization in addicts' lives extends beyond their self-regulatory functions. For example, to support the denial of an inner conflict, addicts (or anyone else) can assign one side of the conflict to an external agent and thereby transform the inner conflict into an external conflict. Or, in an attempt to take magical omnipotent control over their inner lives, they may externalize a passively experienced, traumatic inner state to a tangible external problem that they believe can be resolved through effort and action. A consistent feature of externalization is its direction of attention and energy toward action in the external world.

The DSM-5-TR diagnostic criteria for narcissistic personality disorder (lightly abridged) are: (1) grandiose sense of self-importance; (2) preoccupation with fantasies of unlimited success, power, brilliance, beauty, or ideal love; (3) belief that one is unique and special; (4) abnormal need for admiration; (5) sense of entitlement; (6) interpersonal exploitativeness; (7) lack of empathy; (8) envy of others or belief that one is envied by others; and (9) arrogant behaviors or attitudes. The use in common parlance of *narcissistic* and *narcissist* as terms of disparagement reflects the magnitude of people's antipathy toward narcissistic behaviors and attitudes (or perhaps of their motivation to disavow their own narcissistic problems). It also reflects people's failure to appreciate that these behaviors and attitudes arise as desperate measures to avoid annihilation and persist because they are unconsciously believed to be required as protection against that same danger.

The narcissistic character system is a variable set of self-protective processes that function to preserve one's sense of self from annihilation or fragmentation and to sustain an artificial self-esteem that supports the dissociation of overwhelming shame, humiliation, vulnerability, sense of inadequacy, and helplessness. Grandiosity is the most overt aspect of the artificial self-esteem. It supports dissociation of the aforementioned affective experiences by trumpeting their opposite. Deficient empathy (ability to sense the emotions that another person is consciously or unconsciously experiencing) can result from genetic factors or from isolation in early infancy. However, it most commonly originates early in life as a self-protective deadening of one's empathic sense under circumstances in which experiencing a primary caregiver's emotions entails a threat of annihilation (e.g., by becoming affectively overwhelmed, or by losing a sense of self-other boundary and subjectively ceasing to exist as a distinct self). One's capacity for empathy can be further undermined by impaired ability to recognize or name affects.

A sense of entitlement can originate in grandiose fantasies. More often, it is based on reality. During the first years of life, most if not all persons who later develop narcissistic character pathology did not receive enough of the caring, nurturing, or soothing that they needed for healthy development—and to which they as mammals were biopsychologically entitled by virtue of having been born. In the context of that history, lingering feelings of need, emptiness, deprivation, and entitlement are understandable. Grandiosity may then seep into and swell the entitlement to drive away feelings of need, vulnerability, and helplessness. In general, the problem with entitlement is not entitlement as such, but people's unconscious fantasies that they will receive restitution from people in their current lives for what they were entitled to but did not get in their early childhoods. The main function of this fantasy, like that of the primal fantasy from which it is an offshoot, is to support the dissociation of traumatic early experiences of privation or abandonment.

Individuals whose functioning is structured by the narcissistic character system are unconsciously terrified by the ongoing threats to their psychological survival. They desperately seek and try to control potential sources of narcissistic supplies—whatever might help preserve their beleaguered sense of self or sustain their prosthetic self-esteem. Since they unconsciously experience their survival to be at stake, they tend to relate to other persons primarily in terms of the latter's capacity to provide or interfere with access to such supplies. Addictive behavior patterns can be understood as a natural expression of the characteristic modes of adaptation that individuals with narcissistic character pathology employ to deal with their underlying vulnerabilities and impairments.

In addictive disorders, denial, externalization, and narcissistic self-protective processes support and promote one another. In effect, they operate together as one system of character or personality.

IMPAIRED ABILITY TO SYMBOLIZE AFFECTS. People who struggle with addictive disorders share with psychosomatic disorder patients and post-traumatic stress disorder (PTSD) patients an impaired ability to symbolize affects. They have difficulty recognizing, naming, and verbalizing their affects, which they typically experience as physical bodily states rather than meaningful emotions. These disturbances often are accompanied by a lowered capacity for empathy and diminished emotional involvement in interpersonal relationships. The ability to recognize and identify emotions is a critical component of affect tolerance, which accordingly is diminished when the ability to symbolize affects is impaired. Affects that arise under these circumstances consequently are more often experienced as potentially overwhelming, as incipient threats to the stability of the self. The experience of affects as physical bodily states moreover disposes people to address them by physical means, by action—and particularly by action that directly affects the body.

Episodes of addictive behavior are usually precipitated by painful affects that addicts at some level perceive as threatening to overwhelm them. However, they often are consciously aware of neither the sense of being threatened nor even the affects themselves. Preceding an episode of addictive behavior, they typically experience a nonspecific sense of dysphoria or discomfort—a vague restlessness, uneasiness, and unpleasant sense of tension. Some addicts do not experience the emotional discomfort at all but are aware only of an urge or a craving to engage in symptomatic behavior.

An impaired ability to symbolize affects can result from one or more of the following factors: (1) a primary developmental deficit; (2) regression to a more primitive kind of symbolic and/or affective functioning (regression is reversion to a developmentally earlier mode of being that usually occurs as an unconsciously intended means of self-protection from traumatic emotional pain); (3) a broad-spectrum self-protective process that is directed against affects or symbolic processes in general; and (4) a “walling off” of affect regulation functions, unconsciously reserving them for one’s caregiver or, more accurately, for the caregiver as represented in one’s mind.

THE BASIC CONFLICT. The basic conflict is between two fundamental sets of drives and fears that emerge during the first 2 years of life. On one side is a drive for attachment, connection, or merger with the caregiver, which is combined with fear of being abandoned by or isolated from the caregiver. On the other is a drive for separation, autonomy, and mastery, which is combined with fear of being engulfed, swallowed up, or controlled by the caregiver. In short, the basic conflict can be understood as being between a basic pull toward attachment-union with another person and a basic push toward being a separate, autonomous self.

The importance of the basic conflict derives first of all from its ubiquity. It is not a form of psychopathology but a part of the human condition that pulsates in the background throughout people’s lives. How it manifests depends on the life context and on where a person is developmentally. Examples of forms it can take include conflicts between wishes to be taken care of and fears of being controlled, and between wishes to be competent and fears of being abandoned. In addition to being ubiquitous, the basic conflict is perpetual and unavoidably painful. Both connections with other persons and existence as a separate self are necessary for an individual’s psychological survival, and a move toward one side can evoke painful feelings of threat or loss related to the other. When the basic conflict is not effectively managed, it intensifies any inner conflict that can be mapped onto it. (Management of a conflict does not mean that it has been solved and settled but that relatively stable dynamic equilibrium is being maintained.)

A number of factors can make the basic conflict difficult to manage. Most often, people have difficulty resolving the basic conflict when they unconsciously believe that it is associated with more anxiety than they can tolerate. Perhaps their primary caregivers gave them messages that their connections with their caregivers were contingent on their not being separate persons and that being separate would result in being abandoned. Or their history with their primary caregivers led them to expect that connecting with another person would be too likely to lead to being devastatingly hurt, humiliated, or losing their identity. Or they unconsciously refuse to become separate and masterful because to do so would imply recognition that their unmet early childhood needs would never be met, which would expose them to traumatic depressive pain. One or more of these patterns characterize the early history of most addicts. A more general factor is impaired self-regulation, which can intensify anxiety or emotional pain to the point of feeling as though it were threatening to overwhelm and destroy the subject. The final common pathway is that affected persons unconsciously believe that awareness of the basic conflict would be accompanied by overwhelming, shattering anxiety. Consequently, they avoid that awareness by keeping one side of the conflict out of conscious view. This process of dissociation or splitting is often sustained by unconsciously assigning (i.e., externalizing) the dissociated side of the conflict to another person. The other person is then experienced as though they were pushing for that side of the conflict.

For example, a fictional patient Blake unconsciously wants his psychotherapist to take care of him totally but also fears being taken over and losing his sense of self. Assigning the former side of the conflict to the therapist could lead Blake to experience his therapist as trying to seduce or trick him into becoming dependent while Blake experiences himself as trying to hold onto his autonomy. Conversely, assigning the latter side to the therapist could lead Blake to experience himself as trying to develop a closer relationship with his therapist while the therapist is holding back or pushing him away.

THE PRIMAL FANTASY. The primal fantasy is an unconscious fantasy that can develop during the first 2 years of life when some combination of deficient caregiver responsiveness and a child's genetically or epigenetically based impairments interfere with the fulfillment of the child's needs to be cared for, held, nurtured, and soothed. The fantasy is that those fundamental needs that were not met during early childhood will someday be met. While it is defined by anticipated gratification, its power derives primarily from its capacity to sustain the dissociation of overwhelmingly painful early experiences of privation or abandonment and thus to provide protection from traumatic pain. The belief that unmet needs of early childhood might yet be met enables avoidance of the realization that the opportunity to have those needs met is, along with early childhood, lost and gone forever.

A common form of this fantasy begins with children's implicit belief that the reason their needs were not met was that they were bad or not good enough and thus did not deserve to have their needs met. Their minds gravitate toward this explanation in preference to others that locate the cause of their privation in the primary caregiver or an unpredictable universe. Believing that they themselves are to blame for their needs not being met is painful but believing that they are helpless and can do nothing to influence this condition is even more so. Self-blame sustains illusions of having control. The fantasy then takes over with the belief that if they were to be good enough or do well enough, they would get their needs met. In addition to fostering a sense of efficacy, this belief inoculates the primal fantasy against empirical test. Individuals' failure to get their needs met after being good or doing well does not disprove the fantasy. It just indicates that they were not good enough or did not do well enough.

When people rely on the primal fantasy to protect themselves from the pain of early privation or abandonment, they have a hard time separating from their parents and becoming authentic, self-responsible persons. The fantasy is about meeting the needs of early childhood, so the subject of the fantasy must in significant ways remain in early childhood. As long as people do not grow up, they can maintain the fantasy that the unmet needs of their early childhood still can be met. Growing up, becoming separate and authentic persons, means letting go of the fantasy. The consequent annihilation anxiety leads some individuals to avoid separating from their parents, taking care of themselves, or assuming adult responsibilities.

People typically externalize the primal fantasy onto another person. They at some level believe that important needs that were not met during their early childhood will be met by this person. During their subsequent childhood, this fantasy can increase their vulnerability to being sexually abused. Later in life, it can lead them repeatedly into dysfunctional relationships. Sexualization of the fantasy can turn them toward addictive involvement in romantic relationships or other kinds of sexual behavior. The psychodynamics of addictive disorders in general usually involve the primal fantasy. In such cases, people unconsciously perceive the drug or food, or other objects of the addictive behavior as the fantasy object that will relieve their pain, fill their emptiness, make them whole, and meet in distorted form the unmet needs of their early childhoods.

Development of the Addictive Process. The development of the addictive process in psychological terms can be condensed to: (1) due to some combination of genetic and environmental factors, individuals' self-regulatory functions are impaired; (2) impaired self-regulation leaves them abnormally vulnerable to being overwhelmed by intense emotional states and loss of self-coherence; (3) in attempts to protect themselves from the danger of being thus overwhelmed, they externalize fantasy-tinged mental representations of their self-regulatory functions onto nonself activities or objects over which they believe that they have control. When the behavior that results occurs in a pattern that is characterized by recurrent loss of control and continuation of the behavior despite significant harmful consequences, they can be characterized as “addicts,” whatever the behaviors in which they addictively engage.

SELECTION OF SEXUAL BEHAVIOR

The addictive process represents a predisposition to engage in one or more behaviors that can provide both pleasure and relief in a pattern that is characterized by recurrent failure to control and continuation despite harmful consequences. Given a sufficient degree of predisposition, what determines the specific behavior(s) in which a person addictively engages? More particularly, what might lead a person to choose (unconsciously) a form of sexual behavior rather than, for example, using cocaine or eating?

The development of a particular addictive disorder seems to have three components: (1) by virtue of the addictive process, individuals are predisposed to depend on some kind of pleasure-producing behavior to regulate their (dysregulated) affects and sense of self; (2) they take a mood-altering substance or engage in some other rewarding behavior; and (3) the effects of the substance-taking or other behavior—positively reinforcing, negatively reinforcing, and aversive—and the individuals' expectations about its effects in the future combine to determine the likelihood that they will select to take that substance or engage in that behavior as their addictive behavior of choice. These effects and expectations are determined by both genetic and experiential factors.

The foregoing observation suggests that sex addiction develops in addictively predisposed individuals who experience some form of sexual stimulation and learn to expect that sexual behavior will not only provide pleasure but also relieve the affects that they experience as most dangerous, through means that are congruent with their characteristic modes of adaptation.

Experiences that sexual stimulation provides both pleasure and relief begin early in life. Newborn infants' first and most fundamental experience of pleasure and soothing is not suckling a breast or ingesting milk. It is skin-to-skin contact. This bodily contact supplies warmth, which relieves the first and (usually) most extreme distress of early extrauterine life. It also soothes somatic-affective discomfort and thereby provides a foundation for the subsequent development of affect-regulation. Skin precedes the mouth as the first erogenous zone. As infants develop, their responses to skin-to-skin contact begin to differentiate and become specific to particular areas of contact. Physiologic and behavioral changes that indicate intense pleasure in response to bodily contact in the genital region become increasingly distinct from the pleasure responses to skin-to-skin contact with other areas of the body.

Infant observation studies have reported that at some time between 15 and 19 months of age, both male and female infants normally demonstrate an upsurge in genital self-manipulation. In time this takes on a more recognizably masturbatory pattern. Infants actively produce warm, pleasurable feelings in their own bodies which earlier they only passively experienced through nurturing maternal care. The genital self-stimulation seems from the outset to be mother-directed. During masturbation, children often engage their mothers visually and smile at them. Later they use mother-connected objects, such as nursing bottles or transitional objects, for masturbatory activities. Children’s early sexual interest and activity not only provide pleasure and tension release but moreover (in healthy development) facilitate the consolidation of self and object representations.

From the beginning of life, skin-to-skin sensations and then sexual sensations are intimately associated with survival, mother, and soothing, the last of which is the foundation of affect-regulation. Genital self-manipulation in the second year of life is mother-oriented and influences the development of not only mental representations of emotionally significant others but also sense of self and self-regulation. Significantly, infants are able to engage in sexual self-stimulation and provide the associated pleasurable and soothing feelings for themselves, independent of others’ availability and willingness to soothe them. Not until they are older are they able to obtain and consume food on their own. A subjective drive to provide regulation of one’s inner states by external means that seem to be within one’s own control is at the core of addiction. Freud characterized masturbation as “the primal addiction” from which all other addictive disorders derive.

Early experiences of sexual stimulation that provide both pleasure and relief are practically universal among neurologically intact infants. Yet not all individuals who are addictively predisposed become sex addicts. The eventual development of sex addiction in addictively predisposed individuals typically is associated with either seduction (overt or covert) or maternal sexualization. Sexualization is the infiltration of unconscious sexual fantasy into ordinarily nonsexual behaviors that hence can be used as vehicles for fantasied sexual gratification, which functions not so much to provide pleasure as to protect oneself from potentially overwhelming affect or self-fragmentation.

(In this paragraph and the next, "mother" and "maternal" are intended to refer to the mothering person, whether she be the child's mother or a nonmaternal primary caregiver.) When a woman who unconsciously relies on sexualization for psychological survival becomes a mother, sexualization is a constituent of the matrix in which the mother–child relationship begins. The influence of maternal sexualization on that relationship and hence on the child's early development is typically greater when the child is the same sex as the woman's fantasized sexual object. During infancy, the emotionally and psychologically deprived child experiences the gratifying aspects of the mother's sexualization and overt or covert seduction as though they were the vitally needed but missing nurturance, holding, and soothing. The child comes to identify with the mother's sexualization and seductiveness as a way of preserving the tie to her. Sexual seductiveness may eventually become the child's predominant mode for relating to others and for expressing their desperate hunger for a fulfilling connection with another person.

In short, if the etiology of sex addiction were to be summed up in one brief equation, it would be: sex addiction = the addictive process + maternal sexualization.

TREATMENT

A core element of the medical way of thinking is the distinction between a disease and its symptoms and signs—observable indications of a disease that often result from the body's response to it. According to the understanding of addiction that is presented here, the addictive process is the underlying disease, and instances of addictive behavior are symptoms and signs of the disease. Among the corollaries of the disease-symptom distinction is that treating the symptoms–in this case, instances of addictive behavior–without treating the underlying disease–the addictive process–is likely to be of limited effectiveness. Meanwhile, a distinctive feature of addictive disorders is the frequency with which external and internal consequences of the symptoms exacerbate the disease or interfere with its treatment. An implication of these conditions is that treatment for an addictive disorder is most likely to be effective when it addresses both the symptomatic behavior and the underlying addictive process. Treatment modalities that are directed primarily toward addressing symptomatic behavior are discussed below under the heading, Symptomatic Behavior Management. Those that are directed primarily toward addressing the addictive process are discussed subsequently under the heading, Healing of the Addictive Process.

Symptomatic Behavior Management

A broad range of sexual behaviors can be used addictively, from those that in themselves are natural and benign aspects of healthy life, such as masturbation and consensual adult sex, to those that violate other people and inflict deep and lasting damage, such as sexual abuse of children and rape. The goals of symptomatic behavior management in the treatment of sex addiction vary with the degrees of violation and damage that are associated with the behavior.

At the more violating-damaging end of the continuum, the goal is to prevent any occurrence of symptomatic sexual behavior. At the less violating-damaging end, the ultimate goal is to facilitate addicts' development of capacities to distinguish between healthy and unhealthy sexual behaviors (the latter being those that, if engaged in by this particular person, are likely to be engaged in addictively and lead to harmful consequences) and between healthy and unhealthy occasions of engagement in a sexual behavior that is not in itself unhealthy for this person. In general, engagement in a healthy sexual behavior is unhealthy when its primary motivation (usually unconscious) is to keep some heretofore unconscious mental content from entering awareness.

The middle region is occupied by sexual behaviors that have been identified as unhealthy for this person, either initially or as a result of their having learned how to identify unhealthy behaviors. In this broad area, the goals of symptomatic behavior management are twofold: (1) to prevent the occurrence of symptomatic sexual behavior; and (2) if symptomatic behavior does occur, to bring about its discontinuation before it leads to significant harmful consequences. Symptomatic behavior management consists primarily of behavior mastery training, other cognitive-behavioral techniques, and dialectical behavior therapy (DBT). On occasion, it may also require behavioral modification or endocrinologic medication. While support groups do not constitute treatment, they can be valuable adjuncts that sustain people’s efforts to refrain from engaging in symptomatic behavior.

While discontinuation of all sexual behavior is not a goal of treatment, an initial period of 1 to 3 months during which addicts refrain from any kind of sexual behavior is often a useful launch into treatment. Few if any are able yet to reliably distinguish healthy from unhealthy with respect to either sexual behavior or occasions of engagement in it. During this period of refrainment, self-perpetuating behavioral, neurobiologic, and psychodynamic patterns will have a chance to cool down, and subjective states that symptomatic behavior had functioned to exclude from awareness may begin to bubble in. During such a period of complete sexual refrainment, any instance of sexual behavior can be explored to identify vulnerability factors, triggers, and what the trigger evoked internally that overwhelmed or undermined the person’s control system.

Behavior Mastery Training. Behavior mastery training is a set of techniques that sex addicts can use on their own to help themselves refrain from enacting symptomatic behavior. The three primary techniques are risk management, urge handling, and symptom containment.

RISK MANAGEMENT. Symptomatic sexual behavior is more likely to occur under some conditions than others. Risk management teaches sex addicts to identify factors that increase the likelihood of symptomatic behavior. They then are trained to initiate protection against the influence of these factors before urges to engage in the behavior overwhelm their ability to organize an effective defense.

The first step is to review specific instances of symptomatic behavior in detail while focusing on the thoughts, feelings, and circumstances that led up to the act. Such reviews often can illuminate sequences of steps that culminate in episodes of symptomatic behavior, key features or patterns that different sequences share, and triggers that precipitate the sequences. Once identified, high-risk situations can be avoided or entered only when accompanied. Behaviors that increase susceptibility can be discontinued or restricted. Recognition of risk factors is also facilitated when the addict practices self-monitoring: for example, by keeping a daily journal of situations, times of day, moods, people, activities, and thoughts that are associated with urges to engage in symptomatic behavior.

The earlier in the process leading up to symptomatic behavior that a person's healthy resources can be mobilized, the less likely they are to engage in symptomatic behavior. Consequently, a critical component of risk management is identification of behavioral warning signs. These are behaviors that occur early in a sequence that culminates in symptomatic behavior and thus can be read as signals that such a sequence has already begun (and must be interrupted).

URGE HANDLING. During the course of healing from sex addiction, urges to engage in symptomatic behavior are inevitable. Urge-handling comprises behavioral and cognitive skills that help people who use sexual behavior addictively manage these urges without reverting to symptomatic behavior.

Behavioral skills are actions that can be put into practice. Beyond avoiding an expanded range of risk factors, they include specific protective responses that people can enact when they are exposed to a risk factor—for example, physically leaving a situation, engaging in an activity that precludes the next step toward sexually acting out, or contacting a peer and talking about the situation. Behavioral skills are most effective when planned in advance and rehearsed, since the concentration that formulation and performance of an unfamiliar behavioral plan require may not be available in the midst of a strong addictive urge.

Cognitive skills are methods that people can employ to modify their own thoughts. They include (1) accepting urges to engage in symptomatic sexual behavior as natural accompaniments of the healing process and hence not as signs of inadequacy; (2) recognizing that urges are not imperatives to act but surface manifestations of affects; (3) reviewing the benefits of refraining from symptomatic behavior and the potential negative consequences of engaging in that behavior; and (4) when fantasies of engaging in the behavior persist, prolonging the fantasies beyond the pleasurable experiences and imagining the harmful consequences and accompanying guilt, shame, or humiliation that could ensue. Particularly in the early phases of healing, cognitive skills are most likely to be effective in practice when they have been verbally rehearsed with another person.

SYMPTOM CONTAINMENT. An episode of symptom recurrence begins with an instance of symptomatic sexual behavior and ends when the addict resumes refraining from such behavior before it produces significant harmful consequences. If the behavior continues to the point that it generates harmful consequences, the event is not a recurrence (of symptoms) but a reversion (of health status). Symptom-containment skills are developed in order to prevent a recurrence from becoming a reversion. The goal is to reinstate refrainment before the symptomatic behavior generates significant harmful consequences.

A discussion of symptom-containment skills presupposes that symptomatic behavior can recur and thus seems to imply that recurrences can to some degree be tolerated. Such tolerance may make sense when the symptomatic behavior is visiting strip clubs or masturbating to pornography. But some sexual behaviors, such as rape and sexual contact with children, are so harmful to others that zero tolerance for the behavior is the only reasonable treatment stance. When people who use sexual behavior addictively are not reliably able to restrain themselves from acting on urges to engage in such seriously harmful behavior, treatment begins with behavior modification or endocrinologic pharmacotherapy, or both. These interventions are continued until such time as the patients are reliably able to restrain themselves. If a sex-addicted person who is not reliably able to restrain him- or herself from acting on urges to engage in seriously harmful sexual behavior does not accept a recommendation for behavior modification and/or endocrinologic pharmacotherapy, a clinician would be well-advised not to undertake the treatment of this person. The risks are considerable, and if the patient is not sufficiently motivated to cooperate with a recommendation of this type, the likelihood of significant progress in treatment is too small to justify such risks. The discussion of symptom-containment that follows thus applies only to the treatment of sex-addicted individuals whose sexual behaviors, while far from benign, are not so seriously harmful to others.

Even when motivation is genuine and therapeutic management is competent, symptomatic behavior can recur. However much a sex addict may consciously wish to refrain from symptomatic behavior, a strong unconscious motivation to resume the behavior persists—fueled by the same motivations and self-regulatory impairments that originally drove the addictive use of the behavior. Some combination of emotional stress, narcissistic injury, weakening of internal behavioral controls, and gaps in the external support structure can converge momentarily to shift the motivational balance in favor of resuming the behavior. When such a motivational shift happens to coincide with the availability of an opportunity to engage in the behavior, symptom recurrence is likely.

Like urge-handling skills, symptom-containment skills consist of behavioral and cognitive skills. Behavioral skills are actions that limit the progression of symptomatic behavior and reinstitute healing, such as communicating with one's therapist, getting together with a supportive friend, or attending a support group meeting. Similar to the behavioral skills of urge-coping, those of symptom containment are most effective when they are planned in advance and rehearsed.

Cognitive skills for handling symptom recurrence involve reframing the recurrence or reconceptualizing what having engaged in symptomatic behavior means. A recurrence is most usefully understood not as a sign of failure or the beginning of reversion but as a signal that a change in the addict's self-management program is needed. It represents a combination of affect and availability for which the addict had not yet developed an effective coping strategy. A recurrence thus reframed becomes an opportunity to learn and to improve the therapeutic program. A problem-solving approach is ultimately more effective in containing symptomatic recurrences and promoting healing than is judgmental reproof or self-reproach. In the case of both behavioral and cognitive skills for symptom containment, the sooner after a recurrence that an Intervention occurs, the greater the probability of preventing reversion.

Behavior mastery training conceptualizes urges to engage in symptomatic sexual behavior as signals of disruptive affects that addicts need to develop healthier, more adaptive means to manage. In thus shifting the focus from controlling the behavior to understanding the affects, behavior mastery training provides a natural bridge from behavior management to psychodynamic psychotherapy. It can be imparted in therapeutic groups or integrated into individual psychotherapy.

Other Cognitive-Behavioral Techniques. Cognitive-behavioral therapy (CBT) is a psychotherapeutic approach that conceptualizes psychological problems mainly in terms of maladaptive learning. Treatment focuses on identifying and correcting inaccurate or distorted thoughts as a means of changing maladaptive behaviors and emotional states. Interventions typically are directive, practical, task-oriented, and educative in nature. Through CBT, people acquire new information, develop new ways of thinking and reacting, and learn specific skills that they can use for the rest of their lives.

A variety of cognitive-behavioral techniques in addition to behavior mastery training can be helpful in the treatment of sex addiction. Patients can be helped to identify distorted thoughts that enable them to dehumanize people who are hurt by their symptomatic sexual behavior or to avoid becoming aware of the emotional, relational, and existential ways in which their sexual behavior harms themselves.

Victim empathy training helps patients become aware of how their behavior affects other people's emotional states. The training focuses not only on direct victims on whom the sexual behavior was perpetrated (when it was inflicted on others) but also on indirect victims: people in the patients' lives who have been hurt or damaged as a result of the patients' sexual behavior, other behavior that prepared for or concealed the sexual behavior, and (eventually, perhaps) behavioral symptoms of the patients' character pathology. Patients are helped to become aware of how their symptomatic behavior has caused people about whom they care to have felt or to feel painful emotional states: abandonment feelings, intense anxiety, loss of self-esteem, and so on. The empathically experienced pain and associated feelings of remorse, guilt, or self-hatred can then function as the aversive affects that are associated with symptomatic sexual behavior in the aversive affect induction procedure. The potential usefulness of this variant is limited to patients who are capable of consciously accessible empathic perception.

Most other cognitive-behavioral techniques focus not on the symptomatic behavior itself but on other aspects of a person's life that predispose to reliance on symptomatic behavior as a means of coping with painful affects and unmet needs. Examples of skills training that helps patients to more effectively manage their affects and meet their needs include anger management, assertiveness training, problem-solving, communications training (e.g., learning to speak in the format “When you did *x*, I felt *y*” rather than accusing or blaming), and lessons in how to initiate and maintain healthy sexual relationships.

Dialectical Behavior Therapy. DBT is a variant of CBT that was developed to enable people who suffer from borderline personality disorder (BPD) to manage their emotions more effectively and thereby gain control over their self-harming and self-endangering behaviors. It has been applied also in the treatment of substance use disorders, eating disorders, and sex addiction. DBT understands the core vulnerability in BPD to be emotional dysregulation. Its fundamental objective is to help patients develop skills that enhance emotional regulation and implement them in their daily lives. These skills are organized into four modules: mindfulness skills, distress tolerance skills, emotion regulation skills, and interpersonal effectiveness skills.

Mindfulness skills in DBT are cognitive-behavioral adaptations of Eastern meditation practice and philosophy. They are identified as observation, description, and participation in the present moment effectively and without judgment. Patients are instructed to nonjudgmentally focus their attention on their inner and outer environments and then describe their observations. They also are taught to act with focused attention and a nonjudgmental mind. A version of meditation typically is taught as a means of developing mindfulness skills.

Distress tolerance skills enable patients to experience painful and disruptive feelings that they cannot immediately change without impulsively engaging in maladaptive, self-harming actions in a desperate reach for relief. At their core is learning to practice nonevaluative acceptance of experienced reality: one’s current emotional state(s), the current situation, oneself, and the world in which one lives. The goal is to help patients become capable of calmly recognizing painful or threatening situations and their impact rather than hiding from them or being overwhelmed. They then are more able to make wise decisions about whether to act and, if so, how.

Emotion regulation skills enable patients to reduce their maladaptive emotional reactions to situations in day-to-day life and their tendency to respond to such emotional reactions with impulsive behavior. Patients are taught to (1) identify and describe their emotions, (2) understand the functions of their emotions, (3) reduce their vulnerability to the triggering of impulsive actions by intense emotions, (4) identify and challenge cognitions that lead to maladaptive emotional reactions, (5) identify obstacles to modifying their maladaptive emotional reactions, and (6) increase the frequency of positive emotional experiences in their lives.

Interpersonal effectiveness skills in DBT range from basic social skills to assertiveness and goal-oriented interpersonal problem-solving. They include effective strategies for asking for what one wants, declining requests to do something one does not want to do, and negotiating interpersonal conflict. The skills taught are intended to maximize the chances that a person’s goals in a specific situation will be met while at the same time not damaging either the relationship or the person’s self-respect.

Patients’ histories usually indicate general areas where skills are deficient and thus where skills training may be helpful or necessary. More specific skill deficits and their consequences can be elucidated by chain analysis, a CBT technique that facilitates identification of the factors that promoted or permitted an occurrence of maladaptive behavior. When an instance of self-harming or self-endangering behavior has occurred, the sequence of cues, emotional responses, and cognitions that led up to and followed the behavior are reviewed in detail. The therapist and patient then attempt to determine the specific vulnerability factors and antecedent events that increased the likelihood that the behavior would occur and the consequences that reinforced the behavior. The goal of chain analysis is to identify the patterns of variables that tend to control the patient’s dysfunctional behaviors. This information then guides training in skills that reduce vulnerabilities in the future and lower the risk that precipitating events will recur. Chain analyses in DBT often focus on the various ways in which emotions are related to the initiation and maintenance of dysfunctional behaviors. Attention is directed toward the intense or aversive emotional states that may precede target behaviors as well as the potential emotion regulatory function that such behaviors may serve.

To the extent that DBT helps patients develop skills that enhance their emotional regulation, it contributes not only to symptomatic behavior management but also to the healing of the addictive process.

Treatments to Modify Paraphilic Behavior. As noted earlier, paraphilic disorders and sex addictions are different kinds of disorders that share an area of overlap. For many of the individuals who occupy this area of overlap, failure to address the paraphilic nature of their arousal patterns, urges, and sexual behavior can undermine the effectiveness of treatment for sex addiction. In some of these individuals, those who are paraphilic predators, treatment for sex addiction outside a locked facility may entail too much risk of harm to others unless their paraphilic behavior and sometimes their capacity for sexual arousal are shut down. Worthy of note is that the class of paraphilias includes sexual behavior in which one person coerces another into participation. Such behavior is motivated more by sadism than by craving for sexual gratification. In DSM-5-TR, sexual sadism disorder is included among the paraphilic disorders.

BEHAVIOR MODIFICATION. Behavioral methods are oriented toward helping paraphilic individuals reduce their erotic arousal to paraphilic objects/subjects or shift the balance of erotic arousal potential from paraphilic to nonparaphilic interests. The primary forms of behavioral treatment for paraphilic disorders are aversion conditioning, covert sensitization, masturbatory training, imaginal desensitization, and aversive affect induction. All rely on classical or Pavlovian conditioning, in which the repeated pairing of two stimuli increasingly enables one of them to elicit physiologic and affective responses that previously had been elicited only by the other.

In aversion conditioning, unwanted patterns of sexual behavior are linked repeatedly with unpleasant stimuli, most often electric shock or foul odors. This straightforward classical conditioning procedure is intended to transform stimulus features of the sexual behavior into conditioned stimuli or triggers for the aversive responses to the unpleasant stimuli. A number of uncontrolled studies found that aversion conditioning yielded positive results, while one found no significant effect. Another study found that the success of aversion conditioning depended on the availability of appropriate sexual outlets and the absence of severe nonsexual pathology.

Covert sensitization was developed as an imaginary form of aversion conditioning, in which fantasies of paraphilic arousal are paired with fantasies of aversive events in order to promote a learned association between paraphilic themes and unpleasant feelings. In covert sensitization training, patients are first led through a relaxation exercise, which enhances their receptiveness to vivid mental imagery and helps them to focus their attention on the imagery rather than on external events. They then are instructed to visualize themselves engaging in some aspect of their paraphilic behaviors and are encouraged to feel personally involved. At that point, patients are told to imagine either an unpleasant event, such as nausea and vomiting, or an aversive consequence that could follow the behavior in reality, such as public humiliation or shame at being discovered by someone whose esteem deeply matters to them. The aversive valence of the imagined noxious scene can be reinforced by the presentation of a nauseating odor. Studies have found covert sensitization to be effective in the treatment of exhibitionism and pedophilia. It neither inflicts physical discomfort nor requires expensive technology, and patients can be taught to self-administer the treatment. Consequently, many behavior therapists prefer to begin with covert sensitization, turning to aversion therapy only for patients who do not respond to covert sensitization.

Masturbatory training attempts to shift paraphilic patients’ arousal patterns in the conventional direction by controlling the visual stimuli they view or the fantasies they conjure when they masturbate. The two main forms of masturbatory training are satiation and fading. Satiation involves instructing male patients to masturbate to orgasm with conventional sexual stimuli or fantasies and then to continue masturbating while visualizing their deviant objects. The idea is that masturbating after orgasm will extinguish erotic arousal to paraphilic fantasies. The aim of the fading technique is to shift patients' sexual fantasies from deviant to conventional during periods of sexual arousal. Patients may be provided with a video or sequence of slides on which to focus while they masturbate. As they masturbate, the visual presentation progressively fades from nonparaphilic to paraphilic sexual images. Alternatively, patients may be instructed to begin masturbating to paraphilic fantasies and then gradually evolve the fantasies to nonparaphilic sexual scenarios. One study of masturbatory satiation reported mild success, but other therapeutic modalities were provided at the same time and no post-treatment follow-up was mentioned.

The technique of imaginal desensitization is based on the theory that once an individual has developed a sequence of sexual activity that begins with a sexual thought or fantasy and ends with overt behavior, interruption of the sequence results in anxiety, which then motivates completion of the sequence. Imaginal desensitization uses the methods of systematic desensitization to diminish the anxiety that is aroused by interruption of that sequence. The procedure begins with the patient describing a scene in which they are stimulated to carry out the paraphilic sexual activities for which they sought treatment. After relaxation is induced, the patient visualizes performing a sequence of behaviors that leads to noncompletion of the act. Relaxation is allowed to develop with each visualized behavior before the patient proceeds to the next behavior in the sequence. The patient is thus trained to visualize not completing the sexual act while remaining relaxed. One study reported imaginal desensitization to be more effective than covert sensitization.

Aversive affect induction involves focusing on the negative emotional consequences of symptomatic sexual behavior while the urge to engage in such behavior is active. Specific cues that patients have identified as being associated in their minds with symptomatic sexual behavior (e.g., the home page of a website that features sadistic pornography, the sounds of children playing) are presented to evoke an urge to engage in that behavior. Patients are then asked to describe the emotions that they experience before, during, and after an episode of symptomatic sexual behavior—for example, excitement, power, sexual release, shame, self-loathing. The intent is that associations develop in the patient's mind between urges to engage in symptomatic sexual behavior and narcissistically gashing emotions, such as shame and self-loathing. Aversive affect induction has the potential to be helpful in nonparaphilic sex addiction, but its use in that capacity has not been studied.

ENDOCRINOLOGIC AGENTS. Endocrinologic agents are used primarily to reduce sex drive in paraphilic men. These include progestogens and gonadotropin-releasing hormone (GnRH) agonists. Estrogens have been studied for use in controlling sexual behavior but were found to have too many undesirable effects.

The progestogens used in the treatment of paraphilias include cyproterone acetate (CPA) and medroxyprogesterone acetate (MPA). Their action as progestogens blocks the secretion of the pituitary gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). CPA has strong progestational and antigonadotropic activity. In addition, it competes with androgens for androgen receptors and thus is an antiandrogen. CPA has been reported to decrease sexually driven aggression and to reduce arousal responses to pedophilic and coercive sexual stimuli but not to mutually consenting adult sex scenes. Side effects of weight gain, depression, and feminization have been noted. MPA exhibits no antiandrogenic activity. Its efficacy in treating paraphilias results primarily from its induction of the enzyme testosterone reductase in the liver, which decreases circulating levels of testosterone. A number of clinical studies have demonstrated that MPA can reduce sex drive, sexual thoughts, sexual behavior, and aggressiveness. Unfortunately, its administration is frequently associated with unpleasant side effects and occasionally with serious adverse events such as deep vein thrombosis, pulmonary embolism, hepatic dysfunction, and precipitation or exacerbation of diabetes mellitus. Noncompliance also is a significant problem. One study reported a dropout rate of greater than 50%. Both progestogens are available in oral and IM formulations.

Analogs of GnRH have been developed that have higher potency and longer duration of action than naturally occurring GnRH. Triptorelin is injected once a month and leuprolide acetate is injected once every 3 months. Initial administration of these agents raises serum testosterone by stimulating pituitary gonadotrope cells to increase production of LH and FSH. LH then stimulates testicular Leydig cells to synthesize more androgens. During the first 2 to 4 weeks after initiation of treatment, sex drive may actually increase. However, continuous administration of long-acting GnRH analogs produces downregulation of GnRH receptors on the pituitary gonadotropes. GnRH receptor downregulation leads to decreased secretion of LH and FSH, a consequent decrease in the synthesis of testosterone, and thus a substantial diminution of sex drive. Several reports of uncontrolled open-label trials of GnRH agonists in the treatment of paraphilias and hypersexual disorders have been published, and all demonstrated significant positive effects. The main side effects were erectile dysfunction, hot flashes, and a decrease in bone density. These results suggest that GnRH agonists could prove to be a more effective, safer, and less noxious alternative to the progestogenic agents. More study of these promising agents is warranted.

A review article recommended that endocrinologic agents be used in combination with serotonergic antidepressants, not as monotherapies, and that progestogens be tried before LHRH (GnRH) agonists. Another review reported that patients who had taken CPA, MPA, or selective serotonin reuptake inhibitors (SSRIs) and subsequently took a GnRH agonist reported greater therapeutic benefits from the latter.

Although these medications do not change the direction of the paraphilic person’s sexual interest, they decrease the intensity of sexual drive, so the person is more in control and less likely to engage in paraphilic behavior. The primary therapeutic function of these medications is to reduce sex drive to manageable levels in those individuals whose ability to control their behavioral impulses is so impaired as to put them at risk either to injure themselves or others or to render them unresponsive to psychological interventions. Endocrinologic agents can lower the risk of problematic sexual behavior during the interval between the initiation of treatment and the consolidation of the changes that affect-regulating agents, behavior modification, DBT, and/or psychodynamic psychotherapy can induce. A review article on the treatment of paraphilias concluded that the combination of pharmacologic therapy and psychotherapy is associated with greater efficacy than either treatment alone.

A number of other medications that were developed for other purposes have side effects of decreased sex drive or erectile dysfunction and are on occasion used informally—often by patients on their own initiative and sometimes without informed medical direction—in attempts to reduce the symptoms of sex addiction. These include antihypertensive agents, anticholinergics, antihistamines, disulfiram, antipsychotic medications, and hair growth stimulants. None of these have been rigorously studied for use in controlling sexual fantasies, urges, or behavior.

Support Groups. Support groups are distinguished from treatment groups in that the effective agent is neither a therapeutic method/technique nor a person who leads the group but the support that group members provide for one another. Support groups for sex addicts typically provide a safe, minimally judgmental sanctuary where they can talk about shame- and guilt-laden matters with others whose presence in the group and self-identification as sex addicts indicates that they too struggle with comparable shame- and guilt-laden matters. In such groups, sex addicts can learn from one another’s experiences, identify with others who manage their addiction more effectively or make good decisions more often, benefit from others’ encouragement and positive responses to their successes, and feel compassion for others’ stumbles when they are not yet ready to begin feeling compassion for themselves. When they or others in the group engage in symptomatic behavior (recurrence or reversion) and are welcomed back into the group with neither reprimand nor willingness to hear excuses, they can learn to be more self-accepting and also more honest with themselves. More broadly, sex addiction support groups provide opportunities to experience commonality (the “I’m not the only one” experience), empathic bonding, group cohesiveness, and sense of belonging. They thereby can facilitate the development of abilities to make meaningful connections with others and to turn to people in times of need instead of turning to addictive behavior.

The most widespread and easy-to-access support groups for sex addicts are the 12-step groups that have adapted the model of Alcoholics Anonymous to sex addiction. They offer membership at no charge for as long as a person wishes, around-the-clock support, and connection with a worldwide support network. They present a coherent framework for approaching addictive problems and life in general that includes self-awareness, acceptance of what is, and the centrality of human relationships. In addition, 12-step groups offer (but do not impose) a nonjudgmental, nondogmatic spiritual foundation. Meanwhile, a consequence of the lack of formal leadership structures and internal controls in 12-step groups is that the characteristics of a particular group are shaped primarily by the individuals who attend it. How much a person benefits from and enjoys being in a group is a function of their goodness of fit with the other participants in the group.

Healing of the Addictive Process

The addictive process can be addressed through psychiatric medications that improve affect regulation (which includes regulation of anxiety) or reduce impulsivity and psychodynamic psychotherapy. Meditation and yoga can be helpful adjuncts to the primary treatment modalities. Since the addictive process underlies all addictive disorders, the material in this section is not specific to sex addiction but applies to other addictive disorders as well.

Psychiatric Pharmacotherapy. Psychiatric pharmacotherapy is direct intervention to improve emotional and behavioral self-regulation as well as to treat other symptoms of comorbid psychiatric disorders. In sex addiction, craving and urges to act out are expressions of dysregulated emotional states. Such urges are more likely to be acted out when behavioral regulation is impaired. Consequently, enhancement of affect regulation tends to diminish the frequency and intensity of addictive urges while enhancement of behavioral regulation reduces the likelihood that urges will lead to an episode of symptomatic behavior. Medications that improve affect regulation often also reduce impulsivity, either directly or through their effects on affect regulation.

AFFECT-REGULATING AGENTS. A number of case reports and open-label studies have provided evidence for the efficacy of affect-regulating agents, particularly the SSRIs, in the treatment of paraphilias and nonparaphilic sex addictions, even in the absence of major depression. Some studies found that paraphilic patients with comorbid depression showed a concurrent decrease in paraphilic behavior when their depressive symptoms improved. Agents that have been found to be effective include fluoxetine, sertraline, citalopram, paroxetine, fluvoxamine, nefazodone, imipramine, desipramine, clomipramine, lithium carbonate, topiramate, carbamazepine, divalproex, buspirone, and electroconvulsive therapy. Most of these studies reported a positive response rate in the range of 50% to 90%. One investigator reported anecdotally that augmentation of an SSRI with bupropion or a psychostimulant can further reduce sexual fantasies, urges, and behavior, particularly when symptoms of ADHD are present. Others have found that divalproex or lamotrigine can be helpful for sex addiction symptoms that arise in the context of atypical bipolar conditions or “emotionally unstable character disorders.” Antidepressant medications, especially the SSRIs, can produce diminished libido as a side effect, but a number of studies noted that antidepressants reduced the drive for symptomatic sexual behavior without decreasing the drive for healthy sexual behavior. The only double-blind, placebo-controlled study in this series found that citalopram reduced the frequency of sex addicts’ symptomatic sexual urges, masturbation, and use of pornography while having no significant effect on partnered sexual behaviors. The large number of positive findings is encouraging, but the confidence with which conclusions can be drawn from them is limited by the paucity of controlled studies.

That the symptoms of sex addiction respond to affect-regulating medications in a pattern that resembles the response pattern of affective disorder symptoms is consistent with the earlier description of the addictive process that underlies sex addiction. As formulated neurobiologically, the addictive process originates in impaired affect regulation, impaired behavioral inhibition, and impaired functioning of the motivational-reward system. Addictive urges can be recognized to represent both (1) expressions of dysregulated affect, often a nonspecific tense or irritable dysphoria that is experienced consciously less as an affect than as an urge to do something, usually to engage in symptomatic behavior; and (2) conditioned stimuli for coping responses (responses to cope with dysregulated affect) that have been learned in the context of impaired behavioral inhibition and impaired motivational-reward function. Interventions that enhance affect regulation and behavioral inhibition can thus be expected to diminish addictive craving and symptomatic behavior.

In nontechnical terms, the impairment of affect regulation that underlies addiction can be seen as an imbalance between the intensity of patients' affects, particularly their painful affects, and the capacity of their built-in coping systems. Painful affects, such as anxiety and dysphoria, are not in themselves pathologic or "negative." They are signals that people send to themselves to call their attention to something that is important for their physical or psychological survival. Painful affects become a problem when their intensity overwhelms or threatens to overwhelm a person's coping system. They are then experienced as extreme dangers that must be escaped or avoided and are no longer used as signals. Often patients will not consciously experience the painful affects or even the threats of these affects but will feel only a vague unease. Or they may be closed off to their affects and may experience only bodily states that they interpret as urges to engage in some kind of symptomatic behavior. People who have learned that certain self-initiated behaviors can quell such dangerous affects and prevent the system from being overwhelmed will experience strong urges to engage in these behaviors whenever such affects threaten. This process forms the core of addictive and compulsive patterns of behavior.

Psychiatric medication works by restoring or reinforcing the brain chemistry that is associated with patients' built-in coping systems. Although psychodynamic psychotherapy also can enhance the capacity of their coping systems, patients' accessibility to psychotherapy and to what it can offer may be limited when they are emotionally overwhelmed. To the extent that they shut down or shut out subjective experience because they unconsciously perceive that it threatens their psychological survival, their access to their inner lives will be compromised. Moreover, states of being overwhelmed can disorganize or disrupt cognitive functioning, so they not only are less aware of material with which they can work, but they also are less able to work with the material of which they are aware. When psychiatric medication is effective in establishing a more stable balance between patients' affects and the capacity of their coping systems, the coping systems are less likely to be overwhelmed and patients can better tolerate experiencing their painful affects as affects (rather than as states of emergency). Consequently, they will have more conscious access to their inner states, and their cognitive functions will be more organized and free to operate. These developments provide them with more opportunity to work with their inner states in psychotherapy. Subsequent psychotherapeutic work can then help them to develop healthier, more adaptive ways of regulating and responding to their inner states, which may eventually enable them to manage without psychiatric medication.

MU-OPIOID RECEPTOR ANTAGONISTS. The mu-opioid receptor antagonist naltrexone has been reported to reduce symptoms of “compulsive sexual behavior” as an adjunct to affect-regulating medications, primarily SSRIs. Other studies have found naltrexone by itself to reduce urges and symptomatic behavior in gambling disorder and kleptomania as well as in substance use disorders.

Some reports indicate that it reduces the pleasure that is associated with symptomatic behavior but not the pleasure that occurs in the course of normal living.

Psychodynamic Psychotherapy. Psychodynamic (or psychoanalytic) psychotherapy is a circumscribed dialogue in the context of an intimate relationship between two people, the explicit goal of which is to help one of the participants become more fully self-aware in order to master emotional distress and remedy impairments in social or occupational functioning. The central role of developing self-awareness distinguishes psychodynamic psychotherapy from other forms of psychological treatment. Mastering emotional distress and remedying functional impairment identify this process as treatment, above and beyond the educational and growth-promoting functions that it serves. In short, psychodynamic psychotherapy is a dialogue that fosters self-awareness in order to heal the personality. Its functional core is constituted by three interacting processes: understanding, integration, and internalization.

UNDERSTANDING. Understanding as a component of psychodynamic psychotherapy is verbally mediated knowledge that the psychotherapist imparts in the course of treatment. It is a primarily cognitive process that is not specific to psychodynamic psychotherapy. What is more specific (in addition to the content) is the recognition that patients’ difficulties in understanding or in the practical application of what has been understood may reflect motivational factors that operate outside their conscious awareness. Moreover, psychodynamic psychotherapy regards these difficulties not as obstacles but as opportunities to explore the nature, function, and history of the underlying motivational factors. Both general and specific understanding are useful.

General understanding concerns information about a condition from which a person may be suffering and factors that characteristically contribute to its development. At the beginning of treatment, this process often enhances a person’s capacity and motivation to participate in psychodynamic psychotherapy.

For example, early in the treatment of sex addicts, the psychotherapist can briefly describe in simple terms the psychodynamic processes that underlie sex addiction and other addictive disorders. Such information, first of all, provides an organized array of concepts that can help people name their experiences, find order in them, and integrate them into their cognitive networks. Having words to describe inner states and processes gives the conscious mind a handle by which to apprehend them. Moreover, naming inner realities provides perspective. The part of the mind that names in so doing steps back from the part of the mind that feels. Painful emotions and self-states no longer occupy the totality of a person’s subjective psychic space, so they become less likely to be overwhelmed by them.

As noted earlier, emotions are important self-generated signals. But when they become or threaten to become overwhelming, people experience them as threats to their survival. Their survival instincts then drive them to ward off or shut down their emotions. Insofar as they do so, they are unable to benefit from their emotions’ signal function and the information that it conveys. To the extent that people get perspective and become less overwhelmed, they can begin to experience their emotions as signals rather than as states of emergency. Significant progress down this path usually depends on the integration and internalization components of psychodynamic psychotherapy.

General understanding also offers benefits that are more tangibly practical and specific to addiction. Learning that addictive behavior represents an attempt to ward off painful or disorganizing inner states that threaten to overwhelm the person attenuates the shame and self-loathing that addicts feel in relation to their symptomatic behavior and reduces associated self-destructive inclinations. Hearing that urges to engage in symptomatic behavior are conscious manifestations of anxiety that surges when such threats arise shifts addicts’ focus from fighting the urge to understanding the threat. In consequence, behavioral symptom management becomes less effortful, and addicts become more capable of using psychodynamic psychotherapy effectively.

General information about developmental factors that may have contributed to the genesis of sex addiction provides a framework within which the condition becomes comprehensible, often thereby diminishing addicts' anxiety. Moreover, it reduces the self-hatred or self-punishment that people typically experience when they blame themselves for the emotional pain and functional impairment that are associated with sex addiction.

Specific understanding concerns the patient him- or herself and what actually is going on in their life. The primary focus of specific understanding is the dynamic process that has led up to a particular instance of symptomatic sexual behavior. This process is typically of the following form: (1) impaired regulation of emotional states develops out of the interaction between genetic predispositions and the infant's relationship with their early caregiving environment; (2) specific vulnerabilities develop as the emotions that are evoked by painful or scary childhood events (or less commonly, postchildhood events) are hyperintense to the point of being traumatic due to impaired affect regulation; (3) later in life a current event taps into one of those vulnerabilities in the context of deficient affect regulation and thereby triggers a disproportionately intense emotional response that threatens to overwhelm the person; and (4) a desperate reflexive attempt to protect oneself from this threat precipitates an occurrence of symptomatic behavior.

In general, behavioral symptoms arise as (1) expressions of painful or disturbing emotional states that an impaired affect regulation system is not effectively managing, (2) unconsciously directed self-protective processes that operate to keep such emotional states and inner conflicts out of one's awareness, or (3) a combination of both. In addictive disorders, symptomatic behavior may be the only conscious manifestation of dysregulated emotional states that at an unconscious level threaten to burst into a patient's awareness and overwhelm them. Thus, in addition to being distressful or debilitating, symptomatic behaviors are conveyors of information about patients' emotional states, affect regulation systems, and self-protective processes.

The likelihood of accessing this information is greatest when inquiry focuses on the timing of changes in the symptomatic behavior—when it emerged out of quiescence, got worse, got better, or changed shape. The emergence or exacerbation of symptomatic behavior indicates that some event activated a painful or disturbing emotional state that the affect regulation system was unable to manage. The point of information access is temporal contiguity. Unless the timing of symptoms is random, the occurrence of an instance of symptomatic behavior implies an antecedent change in contextual conditions that (by evoking a potentially traumatic emotional state) led the behavior to occur when it did rather than at some other time. Specification of when the symptomatic behavior occurred guides an investigation of what was going on in the person's life just before the symptomatic act, with an eye toward identifying the event(s) that may have precipitated it.

The process of specific understanding typically is initiated when a patient reports an instance of symptomatic behavior. In the treatment of sex addiction, the initial focus is on symptomatic sexual behavior. As treatment progresses and as the frequency of symptomatic sexual behavior decreases, the focus may expand to other symptomatic or maladaptive behaviors. The process begins with a review of circumstances and interactions that preceded the episode of symptomatic behavior. During this review, antennae are tuned for any event that might have triggered an intense emotional response. Identification of the triggering event usually leads to identification of the emotional response, though on occasion the emotional response is identified first. The goal is to help patients increase their capacity to be aware of disproportionate intensity in their emotional responses before they act, so they can factor it out of their decisions about what actions to take.

Guided by the hypothesis that symptomatic behavior characteristically occurs when an event taps into an area of emotional vulnerability, the investigation readily expands in the direction of exploring the contributory factors that were shaped by personal history and intensified beyond the range of ordinary manageability by impaired affect regulation. As it does so, the therapeutic process shifts beyond understanding to include integration, the next component of psychodynamic psychotherapy to be discussed.

INTEGRATION. Integration refers to a process through which the patient's personality or self becomes increasingly integrated as its various aspects coalesce into a coherent whole. Psychologically, many people are characterized by deficits in integration on several levels. Without conscious intent or awareness, they reflexively engage in a variety of mental processes that function to protect them from emotional trauma. Most of these self-protective processes can be understood as ways of keeping out of people's awareness material that they unconsciously imagine would lead to overwhelming pain or self-fragmentation were they to become aware of it. Such material can include emotions, needs, wishes, fears, inner conflicts, core beliefs, or the self-protective processes themselves. Ultimately, what they are protecting themselves from most of the time are emotions that they fear would overwhelm and psychologically destroy them were they allowed to enter their consciousness.

For example, when people automatically push a need or a wish out of their awareness, they do so usually not because the need or wish is dangerous in itself, but because past experiences of other people's responses to their expressing that need or wish led them to associate it with potentially overwhelming emotions such as disappointment, loss, shame, guilt, rage, or humiliation. Similarly, when people automatically keep an inner conflict unconscious—for example, by allowing only one of its components into awareness at a time—they do so because the conflict is fraught with unbearable anxiety, which in turn develops because choosing one of the alternatives and giving up the other is associated with painful emotions that could be traumatic whichever alternative is chosen. Finally, the self-protective processes that people keep out of their awareness typically are not themselves infused with overwhelming emotion. But if someone were aware that a self-protective process was operating, it would be less likely to succeed in concealing the emotion-laden material that it was unconsciously intended to conceal. Thus, people also (unconsciously) hide their self-protective processes from their inner view.

Self-protective processes are not obstacles to self-awareness that must be torn down for healing to occur. Nor do they constitute a “false self” that must be dismantled or peeled away to liberate and reveal a person’s “true self.” People’s means of protecting themselves from emotional trauma are no less true than the mental processes and material that they keep from consciousness and no less important as potential or actual objects of self-awareness. Exploration of self-protective processes often yields treasure troves of information. In addition, a person’s psychological survival can at times depend on inner processes that protect them from emotional trauma. The goal of treatment is not to get rid of them but to increase the influence of patients’ conscious reason on when and how they operate.

People’s subjective experience and behavior are influenced by conscious thoughts, feelings, and reasoning, and also by emotions, needs, wishes, fears, inner conflicts, core beliefs, and self-protective processes of which they are not consciously aware. When such influences operate outside a person’s awareness, they are not susceptible to being modulated or contextualized by their conscious reason.

The process of integration occurs through consciousness. The critical step is becoming aware of feelings, thoughts, and fantasies that heretofore had remained unavailable to conscious awareness. Consciousness is primarily a verbally mediated process, so becoming aware of what had been going on in one’s mind unconsciously involves the development of associative links between unconscious mental processes and their verbal representations. Such links are the basic elements of integration. They typically develop as a result of temporal contiguity between the occurrence of a heretofore unconscious mental process and the conscious registration of its verbal designation or description.

Psychodynamic psychotherapy promotes integration (1) by providing an intimate interpersonal situation that tends to stir up people’s emotions, needs, wishes, fears, inner conflicts, core beliefs, and self-protective processes; (2) by emphasizing verbal communication and meaning, with both patient and therapist working together to create verbal renditions of the patient’s inner world; and (3) by facilitating identification and working through of self-protective processes that interfere with the flow of experience or communication. It thus provides optimal conditions for patients to link their unconscious mental processes with the cocreated verbal descriptions of them and thus develop the self-awareness that leads to integration.

Psychodynamic psychotherapy is less structured and less directed by the therapist than other forms of psychotherapy. Either from the very beginning or after an initial period during which background information is gathered, the steering wheel is left in or returned to the patient’s hands. Meanwhile, the therapist has at hand an auxiliary set of controls, as in a driver’s education car, so they can take over if for whatever reason the patient becomes temporarily incapable of driving safely. Recognition of this safety feature, which often remains implicit, helps enable patients to take more risks in exploring realms of their mental world with their therapists than they would have done on their own.

The patient’s primary instruction (which may or may not be explicitly stated) is to say whatever occurs to their mind without directing or censoring it, even if it seems irrelevant, trivial, offensive, or embarrassing. Psychodynamic factors outside people’s awareness operate all the time, influencing what they think, say, and do. During most of the time that they are awake, their conscious mental processes also are operating, and they dominate the conscious field of view. The influences of unconscious psychodynamic processes are difficult to discern except perhaps when indirectly embodied in slips of the tongue or symptomatic acts. To the extent that the dominance of conscious reason over patients’ verbal output is softened, the influence of unconscious psychodynamic factors over the content and form of what they say becomes more discernable. As patients' words increasingly reflect the operation of psychodynamic factors, inferences about these factors that are based on what patients say become more productive.

In general, psychodynamic psychotherapists do not set agendas for therapy sessions or direct the flow of the dialogue but try to discover and bring to light their patients' underlying emotions, needs, wishes, fears, inner conflicts, core beliefs, and self-protective processes, as inferred from what they observe in the patients and in themselves. Their primary charge is to offer comments and questions that are likely to expand their patients' self-awareness, directly or indirectly. Comments or questions that can expand patients' self-awareness indirectly include those that identify ways in which patients unconsciously constrain or sabotage the expansion of their self-awareness—usually to protect themselves from emotions that are associated with something of which they (unconsciously) fear to become aware.

Whereas the aspects of a person's self that can become integrated in treatment extend over many years of history, the process of integration occurs in the present and operates with present experience, whatever subject matter is being discussed. The closer the subject matter under discussion is to present experience, the more active and salient the associated emotions are, the more available are underlying psychodynamics to conscious exploration, and the more likely is integration to be potentiated by the discussion. Consequently, psychotherapeutic dialogue tends to be most effective in promoting integration when it addresses issues as they arise in the here-and-now. In the psychotherapeutic situation, the most here-and-now issues are those that concern the relationship between the patient and the therapist. Hence, these issues often are the most productive to address.

Early in life, people begin to develop inner models of self-and-other-in-relationship that organize how they perceive, experience, and respond to other people and also how they perceive and experience themselves in relation to others. These models or mental representations are more than audiovisual recordings. They encompass the somatic and behavioral residues of the complex emotions, needs, wishes, fears, inner conflicts, core beliefs, and self-protective processes that individuals experienced during their interactions with other people or developed in response to such interactions. Their experiences with others in the first years of their lives have the most profound and enduring influence on their models for two reasons that probably are related. Humans are helpless at birth and during their early years depend on their caregivers for their survival. Since what they learn about their caregivers and how to respond to them is literally a matter of life or death, natural selection has favored those who learned quickly and held on tightly to what they learned. Meanwhile, humans are born with central nervous systems that are only partially developed. Most of the remaining development occurs epigenetically during the first two years of life and is shaped by the young humans' interactions with their environment, which during those early years consists primarily of their caregivers. The developmental plasticity of human central nervous systems enables them to be much more specifically adapted to each individual's particular environment than would anything that the genetic code could engineer by itself. As a corollary, the people who constitute a person's early environment have a profound and enduring influence on how the central nervous system develops and subsequently functions.

People's inner models of self-and-other-in-relationship are usually of great value in their early relationships with their primary caregivers, on whom they depend for their survival. Their inner models guide them to act in ways that increase the likelihood that their needs will be met, decrease the likelihood that they will experience traumatic emotional-somatic pain, and in general enhance the chances that they will survive. As people's interpersonal world expands, their inner models continue to be adaptive to the extent that (1) the individuals with whom they are now interacting are similar to those who were around when the models initially developed, and (2) the models are sensitive to the differences between past and present people and can evolve to accommodate to the latter.

Sometimes, however, people’s models of self-and-other-in-relationship are not flexible enough to accommodate the differences between the caregivers whose interactions with them shaped the models and the individuals with whom they now interact—particularly when the models are suffused with anxiety about threats to survival. Under these conditions, people’s inner models may guide them to perceive, experience, and respond to significant individuals in ways that are maladaptive—that cause them emotional distress or impair their social or occupational functioning. Often, such emotional distress and functional impairment are what lead people to seek help.

In psychodynamic psychotherapy, the relationship between the patient and therapist is the stage in which the patient’s inner models reveal themselves. As patient and therapist spend time together, interacting at a level more intimate than ordinary discourse, the emotional significance of their relationship deepens, and the patient’s inner models of self-and-other-in-relationship become increasingly activated. A process develops through which the emotions, needs, wishes, fears, inner conflicts, core beliefs, and self-protective processes that are associated with these inner models and that unconsciously influence the patient’s other significant relationships increasingly affect how the patient perceives, experiences, and responds to the therapist.

The therapeutic relationship, however, differs from other close relationships in a crucial respect. To the extent that their own personal vulnerabilities permit, psychodynamic psychotherapists refrain from reacting with defensiveness, retaliation, withdrawal, sadism, or exploitation of their patients’ words and actions. They recognize that patients’ responses to them always reflect some degree of accurate perception of the therapist and some degree of distortion or disproportion due to the activation of patients’ inner models that are incongruous with the current situation. To the extent that patients’ inner models have participated, opportunities become available for both patient and therapist to learn how those models operate. The therapeutic relationship then provides a safe environment in which the two of them together can explore in real-time the meaning of the patient's responses in terms of their emotions, needs, wishes, fears, inner conflicts, core beliefs, and means of self-protection. This collaborative exploration gives words to the patient's subjective, not-quite-conscious experience of these processes while they still are fresh, thus expanding the patient's awareness of them and promoting their integration into the patient's living narrative. Bringing together in consciousness the various disintegrated aspects of a person's psychic processes gradually heals the personality and enables it increasingly to function as an integrated whole. The net result is a more conscious choice, more flexibility, and more freedom.

The interaction between a patient's inner models and their relationship with the therapist is more complex than was its description in the preceding paragraphs. The activation of the patient's inner models that manifests as distorted or disproportionate responses not only provides information and opportunities to expand awareness. It also opens the inner models to modification through the patient–therapist relationship. This process is an aspect of the third component of psychodynamic psychotherapy, internalization, which is discussed in the next section.

INTERNALIZATION. Internalization is the least understood component of psychodynamic psychotherapy. Originally it is the process whereby young children gradually become able to provide for themselves the regulatory functions that had been provided for them by their caregivers. The development of self-regulatory functions occurs gradually over the course of numerous child–caregiver interactions in which the caregiver responds more or less appropriately to the child's needs for nurturing, soothing, and holding. What is internalized over the course of these interactions is not only self-regulatory functions but moreover a relationship in which a caregiver provides regulatory functions for another who needs regulation. The term *internalization* is a metaphor that represents a combination of procedural learning and classical conditioning that interacts dialectically with people's genetically guided (and epigenetically adjusted) maturation. The capacity for developmental internalization of self-regulatory functions is greatest during early childhood but it continues throughout life.

The function of internalization in psychodynamic psychotherapy derives from its role in the development of self-regulation. A primary means by which psychotherapy promotes the healing of impaired self-regulation is by providing new opportunities for people to internalize self-regulatory functions that they did not adequately internalize during their childhood. Development of affect regulation functions can be facilitated by internalization of therapists' provision of a holding environment, their soothing and enlivening functions, and their treatment of emotions as indications of inner dynamics that deserve attention. Development of self-care functions can be facilitated by internalization of the therapist's nurturing and protective functions, accompanied by internalization of the message that the patient is valued as a person and believed to be worth taking care of. Development of healthy self-governance functions can be facilitated by internalization of the therapist's integrity, respectfulness, nonjudgmental acceptance, and general stabilizing function. Development of self-mindfulness—a central factor in affect regulation, self-care, and self-governance—can be facilitated by internalization of the therapist's actively receptive attention to the patient's words, actions, and empathically discernable emotions. Raw material for internalization is provided not only by the therapists' relationships with their patients but also by how they manage or respond to everything else, including their own affects, intrusions of external circumstances into a session, minor mishaps, medical problems, and personal crises. Worthy of note is that patients' perception of potentially internalizeable material occurs through empathy as well as through the five primary senses.

Psychodynamic psychotherapy is not the only context in which self-regulatory functions can be internalized. Internalization can occur in any significant relationship and also in some group situations. What distinguishes psychodynamic psychotherapy is (1) the depth of the relationship; (2) the therapeutic frame of a dyadic relationship with a person who combines caregiving attributes and authority attributes; (3) the therapist's ability to facilitate the patient's personality integration and thus to minimize the extent to which the patient's projections distort the internalization process; and (4) (as patients have a right to expect) the therapist's level of mental-emotional health.

In psychodynamic psychotherapy with people who suffer from addictive disorders, internalization can be facilitated by these individuals' tendencies to experience their self-regulatory functions as being located in the external world and to seek them there. The very process that drives their maladaptive externalizing behavior may thus be an important facilitator of therapeutic internalization in psychotherapy.

After a detailed discussion of the neurobiologic development of the addictive process, a section on treatment that devotes much more space to talk therapies than to pharmacology may seem to be a non sequitur. However, psychodynamic psychotherapy, DBT, and behavior mastery training are neurobiologic as well as psychological processes. Every psychological event is also a neurobiologic event—a unitary event that can be known and described in either of two ways, psychological/subjective or neurobiologic/objective. An early study reported that fluoxetine and CBT were almost identical in their effects on both symptoms and caudate glucose metabolism in OCD patients. Advances in neuroimaging technology have enabled more recent studies to report more comprehensive and detailed findings on the neural correlates of psychotherapy and of changes that occur in the course of psychotherapy.

Meditation and Yoga. A few decades ago, meditation and yoga were generally regarded as culturally alien fringe activities. Since then, they have become almost mainstream. More importantly, they have been scientifically investigated for potentially beneficial effects on the symptoms of a variety of psychiatric and nonpsychiatric medical conditions. Thus far, rigorous research has not been conducted on the effects of meditation or yoga on sex addiction. However, their well-documented effectiveness as adjuncts in the treatment of other addictive disorders and related psychiatric conditions suggests that they would likely be similarly effective as adjuncts in the treatment of sex addiction. Similar to psychodynamic psychotherapy, the primary goal of yoga and of the meditation described below is self-awareness. All three modalities also share a set of accompanying values: mindfulness, acceptance (of self, of what is), integration, emotional balance, and resilience.

MEDITATION. Published studies have reported meditation to be associated with decreased use of alcohol, cocaine, cannabis, heroin, and tobacco; reduced craving and withdrawal symptoms; prevention of substance use disorders; and decreased binge-eating and emotional eating. It has been reported to be an effective adjunct also in the treatment of depression, anxiety disorders, PTSD, and insomnia. Meditation has been found to correlate with improved self-esteem and increased scores on self-related character scales, high scores on which are associated with a lower risk of personality disorder. It has been reported to improve self-regulation over the life span and especially to improve affect regulation. Research findings indicate that it also enhances executive function, insightful problem-solving, cognitive flexibility, and attentional processing. While meditation is most often practiced individually, one study found that group meditation was more effective than individual meditation in increasing mindfulness and reducing cognitive-behavioral avoidance and impulsivity.

Neuroimaging studies have revealed that meditation improves activation and connectivity in brain areas that are related to self-regulation. It has been reported to increase activation of the ventrolateral PFC, functional connectivity between the PFC and the amygdala, and fractional anisotropy in white matter pathways that connect the ACC to other brain areas. Long-term meditators were found to have larger hippocampal volumes than did nonmeditators, particularly in the subiculum, which plays a significant role in stress regulation. In beginning meditators, meditation was found to induce down-regulation of the left amygdala during emotional processing, which indicates a “top-down” form of affect regulation. In experienced meditators, it was found to induce deactivation of default mode network areas (DMN; medial prefrontal and posterior cingulate cortices, precuneus, medial temporal and inferior parietal lobes) and to weaken functional connectivity between them, but not to influence responses in brain regions that are involved in emotional reactivity during emotional processing—which indicates a “bottom-up” form of affect regulation. Meditation has been reported to stimulate GABA release by the thalamic reticular nucleus and thereby promote GABAergic cortical inhibition, which has been implicated in improved cognitive performance and enhanced emotional regulation.

Meditation is practiced in a variety of forms. The majority involve an intentional focus of attention—for example, one’s own breathing, one’s own movements (e.g., walking meditation), a word or idea, a sound of internal or external origin, or a particular sensation. Patients who have practiced some form of meditation and found it to be helpful are encouraged to continue or resume it. Others can be taught the form of meditation that the Buddha practiced: *Anapana-sati* Yoga, the yoga of breath awareness. Practitioners begin by finding a comfortable upright seated position, usually with their legs crossed. Once settled, they try not to move at all during the entire meditation period (usually 20 to 60 minutes) other than to breathe. The suggested focus of attention is the sensation of their own breath coming in and going out through their noses—more specifically, what the skin between their upper lip and nostrils feels as each inhale or exhale brushes across it. Thoughts and emotions are not banished. When they arise, meditators notice but do not name or describe them, in a manner analogous to noticing clouds that pass across the sky while one’s attention is focused on something closer. When attention wanders to such thoughts or emotions, meditators gently bring it back to their breath. This form of meditation is suggested here because it is simple, direct, and unencumbered. Moreover, it facilitates an experience in which the mind can let go of naming or holding on to what is noticed and remain in the immediacy of the moment.

YOGA. Research findings that concern the effects of yoga on psychiatric disorders and mental functioning are remarkably similar to those that concern the effects of meditation. Yoga has been found to decrease the use of alcohol, tobacco, and cannabis; reduce the risk of developing a substance use disorder; reduce the use of opioids for chronic pain; decrease binge-eating; and decrease eating disorder symptoms in a mixed cohort with diagnoses of anorexia, bulimia, or eating disorder NOS. A review article concluded that, as an adjunct in the treatment of eating disorders, yoga can be an effective method for increasing self-awareness, reflection, and the ability to self-soothe. It has been reported also to be an effective adjunct in the treatment of anxiety, depression, obsessive-compulsive disorder (OCD), PTSD, and ADHD, and to improve quality of life in schizophrenia. Yoga practice has been reported to be associated with increased plasma levels of oxytocin in schizophrenia patients, larger hippocampal volumes, and increased serum levels of BDNF.

That physical exercise in itself is beneficial raises a question about whether the benefits of yoga are due to a particular characteristic of yoga or more generally to the exercise that it provides. One study found that 12 weeks of yoga was associated with greater improvements in mood and anxiety than was a metabolically matched walking exercise. In the yoga group, improved mood and decreased anxiety were positively correlated with thalamic GABA levels. Another study reported that following 8 weeks of yoga practice, participants in the yoga intervention group showed significantly greater improvement in performance on the executive function measures of working memory capacity and efficiency of mental set shifting and flexibility compared with their stretching-strengthening counterparts.

Yoga as a whole consists of physical yoga, the active or intentional component, and mental yoga, the body of yogic knowledge and principles. The latter includes philosophy, ethics, science, and spirituality. Physical yoga includes the poses (*asanas*) that are yoga’s most visible manifestation. In a yoga practice, movements into and out of poses are guided by the breath–each is initiated with either an inhalation or an exhalation. The sequence of poses and movements promotes relaxation, inner integration, and receptivity as well as improving flexibility, balance, and strength. The developmental goal of a yoga practice is to increase the practitioner's bodily self-awareness, breath awareness, and sense of body–mind integration. Its immediate goal is to bring the practitioner to a body-mind state that is conducive to meditation. (The origin of meditation is often ascribed to Buddhism. However, Gautama Buddha was a yogi, not a Buddhist. Prior to his awakening [*bodhi*], he had practiced intensively for years under two consecutive hermit teachers of yogic meditation.)

The form of meditation that was described above can be learned and practiced without much instruction. Some people might find even the foregoing brief description of the process sufficient as a starting point. Learning and practicing yoga require considerably more instruction. Classes and individual teaching are widely available. In addition, considerable information about yoga can be obtained from books or online, and audio–visual instruction is available online and via DVD.

EFFECTS ON THE ADDICTIVE PROCESS. The documented effectiveness of meditation and (separately) yoga in decreasing the use of a variety of psychoactive substances and the frequency of eating disorder symptoms (primarily binge eating) suggests that both of these adjunctive treatment modalities are effecting positive change at the level of the addictive process. Reported changes that address addictive process-related impairments include improved self-regulation (meditation), increased self-awareness and ability to self-soothe (yoga), and improved affect regulation (both). Both meditation and yoga also have been associated with improved executive function, which would support healing of impairments in self-care and self-governance. The beneficial effect of yoga as an adjunct to the treatment of ADHD and OCD suggests that it may improve behavioral inhibition.

Development of a Healthier Lifestyle. A lifestyle is constituted by a profusion of elements, each of which varies along a number of dimensions. Among the more prominent elements are nutrition, sleep, exercise, love relationships, social relationships, work (activity that is motivated by anticipation of its wanted consequences), play (activity that is motivated by enjoyment or pleasure that is inherent to the activity), and creative activity. Many would add spirituality. To illustrate how the term *dimension* is being used here, examples in the area of nutrition include caloric intake, protein intake, frequency of meals, and eliminated foods such as gluten or (for vegetarians and vegans) meat. The most relevant dimensions and the optimal values for each dimension vary from person to person. Complex lifestyle elements concern balances between simple elements, such as the balance between work and play or between social time and solitary time. What constitutes being in balance also tends to vary from one person to another.

People can begin to work on reducing stress in their lifestyles by scanning a span of time for activities, situations, and people that are associated with increased levels of stress. Once a “stressogen” has been identified, they can decide whether to eliminate it, modify it, or leave it as is (when according to their own calculations its benefits outweigh its costs).

Sex addicts’ symptomatic behavior has continued because it was reinforced by its consequences, both gratification and alleviation or evasion of painful affects. Their ongoing capacity to refrain from such behavior is enhanced when their lifestyles include nonharmful activities that produce similarly reinforcing consequences or strongly reinforced activities that preclude symptomatic behavior (or both).

Developing a healthier lifestyle requires more than information about changes that would promote physical or mental-emotional health. It requires deciding to act, taking action, and continuing the action. When this sequence breaks down, the interference may have originated in either maladaptive thoughts and ways of thinking or emotional dynamics that were stirred up by something related to the potential change. Under such circumstances, a brief cognitive-behavioral or psychodynamic psychotherapeutic intervention (respectively) may help patients resume their paths toward more health and balance in their lives.

Prognosis

To date, no outcome studies have been published that evaluate the effectiveness of integrated treatment for sex addiction. Empirical research on almost every aspect of sex addiction is lacking: neurobiology, psychometrics, family history, diagnostic criteria (reliability, coverage, and predictive validity), course of illness, and response to treatments. This deficit may have been due to the unavailability until recently of clear and meaningful diagnostic criteria for sex addiction. It also may have been due to reluctance by many to consider sex addiction as a fit subject for scientific study. Perhaps this chapter and similar publications will stimulate the empirical research that this field so desperately needs.

Although the long-term response of sex addiction to various types of treatment cannot at this time be reliably predicted, a number of factors have been identified that seem to influence the prognosis. These factors can be clustered in three groups: (1) illness factors (that tend to worsen the prognosis), which include early age of onset, high frequency of symptomatic sexual behavior, concomitant use of alcohol or other drugs, and absence of anxiety or guilt about the behavior; (2) healing support factors (that tend to improve the prognosis), which include a stable job, a stable primary relationship, a supportive social network, and availability of appropriate sexual outlets; and (3) personality factors (that tend to improve the prognosis), which include intelligence, creativity, self-observatory capacity, sense of humor, capacity to form interpersonal connections, and motivation for change—which is a function of people's ability to experience themselves as responsible as well as their degree of subjective distress. Prognosis is also influenced by comorbidity with other psychiatric disorders, by the degree of associated character pathology, and by the kind of relationship that develops between an addict and their therapist (or whoever else is most involved in the addict's treatment).

In general, treatment for sex addiction is likely to be most effective when the number of different clinicians (and hence opportunities for splitting) is kept to a minimum. When the psychodynamic psychotherapist is also the clinician who conducts DBT or symptomatic behavior management and (when indicated) prescribes psychiatric medication, patients' psychodynamically based (conscious or unconscious) undermining of the latter modalities is more likely to be effectively managed. At another level, assigning different therapeutic modalities to different clinicians is inconsistent with the integrative intent of the treatment.

Significant healing from sex addiction, as from any other addictive disorder, takes time. Addiction interferes with normal development and corrodes interpersonal relationships. The resulting problems remain after symptomatic behavior has ceased and only then can they begin to be effectively addressed. More fundamentally, as described in the preceding section, the principal constituent of healing from an addictive disorder is healing of the addictive process. The initial phase of this healing, which in addition to the overall goals of treatment focuses specifically on affect regulation and stabilization of sense of self, is estimated to require 3 to 5 years.

Healing is not cure. Sex addiction—like other addictive disorders, most psychiatric conditions, and the majority of diseases in medicine—is not an acute disease that effective treatment can cure but a chronic disease that effective treatment can, with patients' active collaboration, bring into remission. And remission in chronic disease is a provisional condition, the continuation of which depends on patients' maintenance of a healthy lifestyle. However much addicts (of any behavioral type) may have benefited from treatment, most will to some extent remain vulnerable to being overwhelmed by intense affects and loss of self-coherence in situations that would be neither traumatic nor disorganizing for individuals whose self-regulation systems are intact. Sex addicts are particularly likely to experience threats of being overwhelmed by these internal states as urges to engage in sexual behavior. Even after stable remission has been achieved, ongoing health-promoting activity may be required indefinitely to prevent recurrence of symptomatic behavior and preserve the progress that has been made. Healing does not make addicts' underlying pain disappear. It helps them become increasingly able to accept and manage their pain while freeing them to more fully and joyfully live their lives.

ACKNOWLEDGMENT

This chapter represents an update and revision of work done by Dr. Aviel Goodman. We are indebted to him for his work and retain much of his prose in this chapter.

Feeding and Eating Disorders

CHRISTINE C. CALL, PH.D., EVELYN ATTIA, M.D., AND B. TIMOTHY WALSH, M.D.

As their name suggests, feeding and eating disorders are characterized by persistent disturbances in feeding and eating behaviors that significantly interfere with the afflicted individual's life, often by negatively and severely impacting physical health or medical status, impairing psychosocial functioning, and causing intense distress. The psychopathology defining these illnesses manifests most saliently in disordered behaviors, but disturbances in thoughts, attitudes, and emotions are also prominent. Because of the medical complications inherent to feeding and eating pathology, these illnesses are serious and often dangerous, making early identification and intervention particularly important, although, unfortunately, it is not uncommon for them to go unrecognized and untreated.

While the syndromes described within the feeding and eating disorders category center around disordered feeding and eating behaviors, they are also each sufficiently different in etiology, clinical presentation, course, prognosis, and treatment needs to warrant distinct diagnostic criteria. The "Feeding and Eating Disorders" chapter of the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) and its text revision (DSM-5-TR) includes six diagnoses: anorexia nervosa, bulimia nervosa, binge eating disorder (BED), avoidant/restrictive food intake disorder (ARFID), pica, and rumination disorder. The chapter also includes two broad heterogeneous categories meant to capture presentations that are consistent with, but do not meet full criteria for, a formally recognized feeding and eating disorder: other specified feeding and eating disorders (OSFED) and unspecified feeding and eating disorders (USFED). Feeding and eating disorders appeared in one comprehensive section for the first time in DSM-5, as they were previously described in separate sections. Feeding disorders have received significantly less research attention than eating disorders, although since the merging of the two sections in DSM-5, feeding disorders (in particular ARFID) have received increased research attention. Because of the limited data available, this chapter will not discuss aspects of feeding disorders that remain poorly understood, including etiology and course.

DEFINITIONS

The definitions of feeding and eating disorders provided below are meant to introduce the reader to each syndrome, but diagnostic criteria and clinical characteristics are discussed in detail in the "Diagnosis and Clinical Features" section of this chapter.

Anorexia Nervosa

Anorexia nervosa is marked by significantly low weight based on developmental trajectory and height. Individuals with this disorder exhibit a persistent and relentless drive for thinness, leading to behaviors that cause weight loss or (particularly in later phases of the illness and for adolescents who are still growing) prevent weight gain. Most prominently, individuals with this illness significantly restrict their food intake, but may also engage in other behaviors that impact weight, including purging (e.g., self-induced vomiting, laxative, diuretic, or enema use), and intense and often compulsive exercise. Individuals with anorexia nervosa demonstrate a strong fear of gaining weight or becoming fat and typically describe body image distortions, believing that they are fat or large even at a low body weight. Weight and shape tend to become essential in self-evaluation, taking over the majority of the individual's self-schema. In addition, individuals with this illness often fail to recognize the medical implications of their current weight status.

Bulimia Nervosa

While sharing certain core features with anorexia nervosa, bulimia nervosa is defined by recurrent episodes of binge eating followed by compensatory behaviors, which might include self-induced vomiting, laxative, diuretic, or enema use, intense exercise, fasting, and medication misuse. Central to the conceptualization of bulimia nervosa is the definition of binge eating, a term that refers to the consumption of an unusually large amount of food accompanied by a sense of lack of control, or the feeling that one cannot stop eating. Individuals with bulimia nervosa maintain their weight at or above normal range for age and height but, similar to those with anorexia nervosa, exhibit intense preoccupation with shape or weight. They often rely almost entirely on these factors in self-evaluation, which typically leads to harsh self-judgment.

Binge Eating Disorder

Individuals with BED, like those with bulimia nervosa, experience repeated episodes of binge eating. However, different from the behavioral pattern of bulimia nervosa, these episodes are *not* followed by compensatory behaviors. While individuals with BED may, and often do, attempt some level of dietary restriction outside of binge eating, they do not engage in inappropriate behaviors meant specifically to compensate for an episode of overeating, like purging or fasting. Individuals with this disorder also maintain their weight at or above the normal range for age and height (and, often, weight is in the overweight or obese category).

Avoidant/Restrictive Food Intake Disorder

ARFID is characterized by persistent disturbances in eating behavior, leading to clinically significant consequences (e.g., nutritional deficiencies, psychosocial impairment, etc.). The restrictive eating that marks this disorder may arise for a variety of reasons (e.g., concern or disgust with texture/consistency/smell of specific food items, anxiety around eating due to a history of choking, vomiting, or a pattern of extremely stressful mealtimes). Notably, shape or weight concern must not motivate the restrictive behaviors as it does in anorexia nervosa and bulimia nervosa. Likewise, a diagnosis of ARFID should not be made if the relevant behaviors occur solely in the context of a separate disorder (e.g., a neurodevelopmental disorder), unless the behaviors are severe enough to warrant specific clinical attention. Finally, feeding or eating behaviors that are considered culturally or socially appropriate should not be considered in making a diagnosis of ARFID.

Pica

Individuals with pica repeatedly consume nonfood items (e.g., paper). As with ARFID, this disturbance must occur outside of the context of culturally sanctioned practices or pre-existing medical or psychiatric conditions that would cause this behavior (e.g., a neurodevelopmental disorder) unless the behavior is so impairing that it requires additional, specific clinical attention.

Rumination Disorder

Individuals with rumination disorder repeatedly regurgitate food and then spit it out, rechew, or reswallow it. Rumination disorder cannot be diagnosed in the presence of anorexia nervosa, bulimia nervosa, BED, or ARFID, although the behavior of rumination often occurs in the context of these syndromes. Likewise, individuals with other medical or psychiatric conditions should not receive a diagnosis of rumination disorder unless the behaviors cause substantial impairment sufficient to necessitate specialized intervention.

Other Specified and Unspecified Feeding and Eating Disorders

Finally, DSM-5 includes two broad, heterogeneous categories meant to capture clinically significant feeding or eating disturbances that do not clearly fall within one of the diagnostic categories outlined above. OSFED provides descriptions of disorders that are not yet formally recognized due to insufficient research describing and characterizing them, or those that are similar to the formal eating disorder categories without meeting the frequency or duration criteria needed for these diagnoses. For example, purging disorder, in which an individual engages in repeated purging behavior without the binge episodes that mark bulimia nervosa, is briefly outlined within the category OSFED. Also outlined within this category are atypical anorexia nervosa, bulimia nervosa of low frequency and/or limited duration, BED of low frequency and/or limited duration, and night eating syndrome. USFED, on the other hand, exists to capture individuals whose behaviors and symptoms are not adequately described by a formal feeding or eating disorder, or by the examples provided in OSFED.

History

Although the specific diagnostic criteria describing feeding and eating disorders continue to shift over time as research findings help guide the current understanding of these illnesses, historical accounts of disordered eating date back as far as the 4th century. Some of these early descriptions appear remarkably similar to the currently accepted definitions of feeding and eating disorders. Still, several of the syndromes now classified as feeding and eating disorders were not officially recognized until much more recently, with BED, only formally accepted as an eating disorder in DSM-5 in 2013, being an excellent example.

Anorexia Nervosa

Anorexia nervosa is the oldest recognized feeding or eating disorder, perhaps because the characteristic low weight that defines the illness has made it more easily discernible over history. The disorder was first formally characterized and named in the 1860s and 1870s by Sir William Gull in London, who coined the name anorexia nervosa, and Dr. Charles Laségue in France, who referred to it as anorexia hysterique. Both physicians described cases of individuals presenting at markedly low body weights and engaging in self-starvation behaviors.

Although Sir William Gull and Dr. Charles Laségue were the first to clearly document reports of the illness, instances of anorexia nervosa likely occurred well before the mid-1800s. In

1689, Richard Morton described a young woman with amenorrhea and significant weight loss, which he ascribed to her mental state. Evidence of self-imposed starvation, often for religious purposes but nonetheless quite severe, dates back to the fourth century, when the gnostic sect of Christian men, believing that material objects including food were evil, engaged in strict and intense fasting practices. Similarly, the term "Holy Anorexia" refers to the practices of numerous women during the Middle Ages (many canonized by the Catholic Church as saints in the 14th and 15th centuries) who strove for holiness by denying themselves food, the self-starvation seeming to become self-sustaining and often resulting in premature death. While it is unclear whether the motives behind these accounts of self-starvation were at all related to body image or feelings about shape or weight, it is nonetheless interesting to note that the most prominent behavior in the current conceptualization of anorexia nervosa, severe self-imposed food restriction, has occurred throughout history.

Since Sir William Gull and Dr. Charles Laségue presented the first clear clinical descriptions of the syndrome, the search to understand this pernicious illness has taken a variety of turns. In the late 1800s, anorexia nervosa was temporarily confused with postpartum pituitary necrosis, leaving a lasting, even if disproved, assumption that some primary abnormality of endocrine function was implicated in the illness's origin. At the beginning of the 20th century, early psychoanalytic hypotheses proposed that the illness might develop from fears of oral impregnation and related themes. Starting in the 1950s, Hilda Bruch formulated a more contemporary psychodynamically oriented hypothesis. Finally, in the 1960s, researchers including Gerald Russell, Arthur Crisp, and Pierre Beaumont initiated the first empirical studies of anorexia nervosa, launching the modern-day understanding of the syndrome.

As research on anorexia nervosa has grown, modifications to diagnostic criteria have been made to better capture the illness. Most recently, DSM-5 featured minor clarifications and modifications to the diagnostic criteria. Perhaps most notably, the DSM-IV criterion that requires an individual to exhibit amenorrhea for at least 3 months to qualify for a diagnosis of anorexia nervosa was removed in DSM-5. The current wording now allows women who report regular or irregular menstrual activity to receive a diagnosis. This change came after several research studies found that women who met all other diagnostic criteria for anorexia nervosa but continued to menstruate regularly did not differ significantly from women meeting full DSM-IV criteria for the syndrome in terms of course, prognosis, or illness severity.

In addition to the deletion of the amenorrhea criterion, DSM-5 and DSM-5-TR feature a clarification to the language describing weight status in anorexia nervosa. This small change aims to eliminate the misunderstanding that "low weight" is defined by one particular body mass index (BMI) or percent ideal body weight (IBW) cutoff. Because assessing weight status is crucial to making a diagnosis of anorexia nervosa, DSM-IV provided 85% of IBW as an example of low weight within the diagnostic criteria for anorexia nervosa. Unfortunately, this specific number was often interpreted as the definition rather than an example of low weight, leading individuals who may have qualified for a diagnosis of anorexia nervosa but presented at greater than 85% of IBW to instead receive a diagnosis of EDNOS. DSM-5 has therefore removed the reference to 85% IBW and has added additional information to the text about determining whether the individual's weight is significantly low by taking into consideration factors including age, developmental trajectory (i.e., where a child or adolescent falls on their individual growth curve), weight history, and medical complications.

Finally, the diagnostic criterion describing fear of weight gain was modified so that individuals who do not endorse or articulate this facet of the illness, but nonetheless demonstrate persistent behaviors that interfere with weight gain or maintenance, may receive a diagnosis of anorexia nervosa. This clarification is meant to capture children and adolescents who may not express this fear due to their age and developmental status, or individuals who, for other reasons (including cultural differences), deny fat-phobia.

Bulimia Nervosa

Bulimia nervosa was formally delineated much later than anorexia nervosa, but it, too, was likely present well before its first official documentation. Although historical accounts of the behaviors associated with bulimia nervosa are not nearly as common as those of the self-starvation inherent to anorexia nervosa, a number of ancient medical texts refer to overeating and subsequent purging. Moreover, given the secrecy that surrounds the syndrome and the lack of easily observable physical indications of the illness (as in anorexia nervosa), it would not be surprising if cases went unnoticed for quite some time before the disorder was formally recognized. Even today many cases of bulimia nervosa go unrecognized because the afflicted individuals maintain normal weight throughout the duration of the disturbance and often hide their disordered behaviors out of shame.

In 1979, Gerald Russell gave a name to the behavioral pattern that was being reported with increasing frequency at the time—episodes of binge eating followed by inappropriate compensatory behaviors. At first, bulimia nervosa, as he named it, was viewed as a variant of anorexia nervosa, but it was quickly recognized that, although the disorders overlap in certain ways, the two are distinct. In 1980, bulimia nervosa was included alongside anorexia nervosa in DSM-III.

Since its formal inclusion in DSM-III, diagnostic criteria for bulimia nervosa have remained largely unchanged, although, notably, there were minor changes made in DSM-5 that aim to reassign individuals classified as EDNOS in DSM-IV into a more appropriate and descriptive category. The primary modification involves the frequency of binge eating and purging behaviors. To meet DSM-IV criteria for bulimia nervosa, individuals must engage in binge eating and inappropriate compensatory behaviors at least twice per week on average for 3 or more months. Since the publication of DSM-IV, research has shown that individuals who exhibit these behaviors once per week on average do not differ clinically from those who experience them more frequently. Thus, in DSM-5, the threshold frequency of binge eating and compensatory behaviors was reduced to once per week for a diagnosis of bulimia nervosa.

Binge Eating Disorder

Interestingly, the behavioral pattern that defines BED, recurrent episodes of binge eating without any inappropriate compensatory behaviors, was clearly characterized in 1959 by Albert Stunkard, two decades before Russell described bulimia nervosa. Despite being documented much earlier than bulimia nervosa, BED began to receive attention and was formally recognized much later. In fact, BED did not appear in the DSM until its fourth edition (DSM-IV) in 1994, when it was described in the appendix as an example of an eating disorder not otherwise specified (EDNOS). Significant research focus on the disorder over the following two decades led to its formal recognition as an eating disorder in DSM-5. From DSM-IV to DSM-5, diagnostic criteria for BED also shifted in parallel to the shifting criteria for bulimia nervosa; individuals who engage in binge eating at least once per week (instead of 2 or more times per week) for 3 or more months now meet full diagnostic criteria for BED.

Avoidant/Restrictive Food Intake Disorder, Rumination Disorder, and Pica

The predecessor to ARFID (feeding disorder of infancy or early childhood), along with rumination disorder and pica, were categorized as feeding and eating disorders of infancy and early childhood in DSM-IV. Their shift into the DSM-5 “Feeding and Eating Disorders” chapter demonstrates the growing awareness that these disorders can occur throughout the lifespan, not just in infancy and early childhood. Besides the removal of the age requirement for these disorders, the diagnostic criteria for pica and rumination disorder remain essentially unchanged from DSM-IV to DSM-5. The diagnostic criteria for ARFID, on the other hand, were substantially expanded in DSM-5 to account for evolving research. In DSM-5, an individual may receive a diagnosis of ARFID even outside the context of weight loss or growth impairment (diagnostic criteria in DSM-IV) provided that the problematic eating behaviors significantly interfere in some other way. (In DSM-5-TR, criterion A was slightly reworded to make clear that interference with psychosocial functioning is sufficient to satisfy this criterion.) DSM-5 also expanded the definition of this disorder by allowing individuals with a comorbid medical condition to receive a diagnosis of ARFID if their eating behavior and subsequent impairment warrant it. Finally, the DSM-5/DSM-5-TR criteria for ARFID recognize motivations for the restrictive eating behavior not previously delineated in DSM-IV’s definition of feeding disorder in infancy or early childhood. In addition to the reasons for food avoidance or restriction described in DSM-IV, such as staying away from foods with certain sensory characteristics or demonstrating a lack of interest in eating in general, DSM-5/DSM-5-TR describes concerns with aversive consequences of eating as another possible explanation of the behaviors observed in ARFID. This concern may stem from experiencing a negative food-related event (e.g., choking or observing someone choke while eating) or from an emotional disturbance surrounding eating (e.g., a history of particularly problematic and difficult mealtimes due to a poor relationship with the caregiver).

COMPARATIVE NOSOLOGY

Currently, two major systems are widely utilized in the diagnosis of mental disorders: The DSM, published by the American Psychiatric Association (APA) and considered the standard classification system in the United States, and the International Classification of Diseases (ICD), published by the World Health Organization (WHO) and used by a significant number of countries worldwide. The most recent edition of the DSM (DSM-5-TR) was released in 2022, following DSM-5 in 2013, and the most recent edition of the ICD (ICD-11) was presented at the World Health Assembly in 2019 and formally replaced ICD-10 starting January 1, 2022. The diagnostic criteria for feeding and eating disorders are largely consistent across DSM-5-TR and ICD-11, although there is a notable difference in the conceptualization of binge eating, as described later in this chapter. (Notably, when the United States will officially adopt the ICD-11 coding scheme is unclear. The ICD-10 codes were adopted only in 2015, more than 20 years after their approval by WHO.)

EPIDEMIOLOGY

Feeding and eating disorders cut across demographic divides, affecting males and females of all ages, races, and cultural backgrounds, although certain demographic characteristics impart higher risk for each syndrome. With the broadening of diagnostic criteria in DSM-5, more individuals fall into a formal feeding or eating disorder category than before, as a notable portion has been reassigned from the broad heterogeneous other and unspecified categories that previously accounted for over 50% of eating disorder cases. Nonetheless, feeding and eating disorders are relatively rare when compared to more common psychiatric conditions, like major depressive disorder. Although a large proportion of the population will, at some point, experience body dissatisfaction and engage in dieting behaviors, a much smaller percentage will struggle with clinically relevant problematic eating and weight-related cognitions and behaviors, and an even smaller subset will meet full criteria for a feeding or eating disorder. Recent estimates suggest that the lifetime prevalence of any eating disorder is approximately 8% in women and 2% in men. Table 22–1 provides an overview of the epidemiology of anorexia nervosa, bulimia nervosa, and BED. Data on the epidemiology of ARFID, pica, and rumination disorder are not included in Table 22–1 as these diagnoses have not yet been assessed in large-scale population-based studies. Preliminary data about their prevalence in specific subpopulations are included in the sections below.

Anorexia Nervosa

Although a substantial proportion of those diagnosed with subthreshold anorexia nervosa in DSM-IV now receives a formal diagnosis in DSM-5-TR, combined rates of subthreshold and threshold anorexia nervosa have remained relatively stable since the 1970s. Various studies have, however, documented a significant increase in incidence rates (the number of new cases in the population over a set period of time) in the high-risk group of 15- to 19-year-old females in recent years. It remains unclear if this increase signifies an earlier age of illness onset or earlier recognition and intervention. Across all age groups and genders, recent epidemiologic studies suggest that lifetime prevalence (the proportion of individuals who have the illness at any point in their life) of DSM-5 anorexia nervosa is about 1.4% in women and 0.2% in men. Among girls and women, point prevalence (prevalence at a specific point in time) of DSM-5 anorexia nervosa is approximately 0.5% to 1%. In a recent study, the 12-month prevalence estimate for anorexia nervosa was 0.05%, which is much lower than prior estimates for reasons that are still unclear.

Although epidemiologic studies indicate that it may occur approximately 10 times more frequently in females, anorexia nervosa does affect males. Recent research suggests that the illness, which continues to be perceived by many as a female disorder, may be even more common in men and boys than previously believed. It may go unrecognized in men for a variety of reasons. In particular, men may be reluctant to seek treatment out of shame, and clinicians may be less likely to recognize the syndrome in male versus female patients. Men may also present with different symptoms than women, such as a drive for both muscularity and leanness (i.e., the muscular ideal) and the inappropriate use of performance-enhancing drugs (e.g., anabolic steroids) to achieve muscularity, which may contribute to underdetection by clinicians. Additionally, while anorexia nervosa has been thought of historically as a disease of white, wealthy women, it impacts individuals of all racial and socioeconomic backgrounds.

Bulimia Nervosa

As with anorexia nervosa, rates of bulimia nervosa have increased with changes to diagnostic criteria. However, overall, studies suggest that the incidence of the illness has decreased in recent years. It is estimated that lifetime prevalence of bulimia nervosa is approximately 2% in women and 0.6% in men, and point prevalence is about 1.5% in women and 0.1% in men. 12-month prevalence was recently estimated at 0.14%, which is lower than prior estimates for reasons that are unclear. Average age of onset also seems to have decreased, although this finding may be an artifact of earlier detection. Like anorexia nervosa, the disorder is more common in women than in men.

Binge Eating Disorder

BED is the most common eating disorder and the least gender-divided of the three. Lifetime prevalence of BED has been estimated at 1% to 3% for women and 0.5% to 1.0% for men, while point prevalence is approximately 0.5% in women and roughly half of that in men. Twelve-month prevalence was recently estimated at 0.44%. Rates of BED are particularly high in individuals with BMIs in the overweight or obese range.

Table 22–1.
Epidemiologic Features of DSM-5-TR Eating Disorders

	Anorexia Nervosa	Bulimia Nervosa	Binge Eating Disorder (BED)	Other Specified Feeding or Eating Disorder (OSFED)
Approx. Lifetime Prevalence	Women: 1.4% Men: 0.2%	Women: 1.9% Men: 0.6%	Women: 1.0–3.0% Men: 0.5–1.0%	7.4%
Approx. Mortality Risk	6 × greater than in general population (1 in 5 from suicide)	1.5–2× greater than in the general population (however, this may be influenced by lifetime history of anorexia nervosa)	No clear increased mortality risk, but increased risk of obesity	Likely varies by presentation
Typical Age of Onset	Early-mid Adolescence	Late adolescence-young adulthood	Young-mid adulthood	Varies by presentation

Avoidant/Restrictive Food Intake Disorder

Less is known about the epidemiology of ARFID. Extant data suggest that prevalence rates range from 0.3% (3-month prevalence) to 3.2% (point prevalence). Within neurogastroenterology clinics, prevalence rates are higher (e.g., among adults, over 6% with a threshold ARFID diagnosis, and over 17% with subthreshold or unconfirmed ARFID diagnosis). ARFID appears to onset at an earlier age than anorexia nervosa, bulimia nervosa, or BED. Additionally, individuals with ARFID, compared to those with an eating disorder, are more likely to present with a co-occurring medical problem and to have a longer illness duration prior to presenting for treatment. Some studies have also reported that, unlike in eating disorders, ARFID occurs more frequently in males than females.

Rumination Disorder and Pica

Epidemiologic data on rumination disorder and pica are particularly limited and results are variable. Self-report measures have found point or 3-month prevalence estimates of rumination behavior ranging from less than 1% to over 10% in adults, and between approximately 1.5% and 5% in children. Prevalence estimates of pica are even more limited, with studies suggesting that this disorder is present in approximately 1.7% to 5% of children. Rumination disorder and pica appear to commonly co-occur with ARFID and with eating disorder symptoms, but additional research is needed on the epidemiologic features of these disorders.

ETIOLOGY

Our current understanding of the specific causes of feeding and eating disorders is limited. Research regarding the etiology of eating disorders suggests that a confluence of factors, including genetic, biologic, psychological, and environmental factors, likely contributes to the onset of these illnesses. However, the precise mechanisms of causation remain elusive. Most studies investigating the etiology of feeding and eating disorders examine individuals who are already afflicted. Yet, the disorders themselves have such a profound impact on biology and psychology that separating cause from effect proves difficult. Moreover, the relatively low frequency of these disorders makes longitudinal studies that examine individuals before and after illness onset challenging, as a very small portion of the original sample will go on to develop a feeding or eating disorder. Despite these obstacles, studies have allowed investigators to identify risk factors and form research-informed theories about the cause of these syndromes.

Current theories posit that individuals with eating disorders possess a set of predisposing traits (e.g., biologic, genetic, and/or personality vulnerability) which, when triggered by a precipitating event (e.g., the stress of puberty, the decision to go on a diet), result in the illness. Once the illness sets in, several factors work to maintain it (e.g., the social rewards of weight loss, the effects of the starvation state in anorexia nervosa). For example, a young woman with a family history of anorexia nervosa (predisposing factor) may decide to go on a diet (precipitating event) with her friend. While the friend, with no genetic predisposition to the illness, may successfully lose a few pounds before her weight stabilizes, the young woman's initial weight loss may quickly spiral into a state of severe, continued restriction and marked weight loss. Once at a low weight, the obsessional thinking common to the starvation state, along with other factors, may serve to sustain the cycle of restrictive eating (maintaining factor). A discussion of the current understanding of the etiology of feeding and eating disorders, and the gaps within, is detailed below.

Anorexia Nervosa

Genetic and Biologic Factors. Several lines of evidence demonstrate that genetic vulnerability plays an important role in the development of anorexia nervosa. In recent years, the Psychiatric Genetics Consortium has developed genome-wide association studies (GWAS) in eating disorders and, to date, has identified eight loci that contribute to the genetic risk for anorexia nervosa. These studies have also established genetic correlations between anorexia nervosa and other disorders, like anxiety disorders. Relatedly, studies of the serotonin transporter offer preliminary evidence that this gene may interact with environmental stressors to play a role in the development of anorexia, emphasizing that a convergence of elements is necessary for illness development. Prior to the emergence of GWAS in eating disorders, family studies provided useful information about genetic susceptibility to anorexia nervosa, demonstrating that individuals with a family history of the illness are much more likely than those with no family history to receive a diagnosis during their lifetime. In fact, the risk of developing the illness is up to 11 times greater in individuals with a first-degree relative who has experienced the illness. Risk is also increased if a relative has a history of a different eating disorder. Twin studies have demonstrated that concordance rates of anorexia nervosa are substantially higher in monozygotic (identical) twins as compared to dizygotic (fraternal) twins, suggesting that something more than family environment is at play in increasing the odds of illness development. Finally, once the illness sets in, the biologic and psychological changes to the body that occur in the starvation state, including low mood and increased obsessionality, may help to maintain the illness.

Developmental Factors. Anorexia nervosa tends to develop during adolescence, suggesting that factors particular to this period may put individuals at risk for the syndrome. Adolescence represents a time of increased biologic, psychological, and social change. The experience of going through puberty and experiencing changes to body shape and weight may serve as a major stressor for some, triggering or worsening body dissatisfaction and low self-esteem. Research suggests that this trend may be particularly true for individuals who enter puberty earlier than their peers. Weight-related teasing and bullying may become increasingly prevalent at this time, as well, exacerbating the issue. Some studies also suggest that hormonal changes during puberty, specifically in estrogen levels, may play a role in eating disorder development, although this has not been firmly established. Finally, a number of major social and psychological transitions occur throughout adolescence, including identity and role formation, increasing independence from parents, and the initiation of romantic relationships. These stressors and others may work to catalyze the eating disorder.

Psychological and Behavioral Factors. Several psychological factors appear to confer added risk for developing anorexia nervosa. Certain personality traits including high levels of perfectionism, self-discipline, harm-avoidance, and self-criticism are common in individuals with the illness. Individuals with the restricting subtype, in particular, exhibit low impulsivity and are much more likely to delay rewards than individuals without the illness. Cognitive inflexibility is usually prominent, as well. In a subset of individuals, mood and anxiety disorders or symptoms precede the development of the anorexia nervosa. Obsessive-compulsive disorder (OCD) and obsessive-compulsive personality traits also appear to serve as vulnerability factors. In recent years, the habit hypothesis of anorexia nervosa has also garnered initial support. This hypothesis posits that when the behaviors responsible for extreme weight loss in anorexia nervosa emerge, they are typically goal-directed and reward-driven. However, over time they become automatic, fixed responses to certain cues (i.e., habitual). Neuroimaging data support this hypothesis by demonstrating that in patients with anorexia nervosa (compared to healthy controls), food choice is mediated by the dorsal striatum, an area that has long been implicated in habitual behaviors.

Environmental and Social Factors. Environmental and social factors small and large, from experiences in the family or school setting to cultural ideals, may play a role in the development of anorexia nervosa. The influence of family functioning style as a potential predisposing factor remains controversial. No single specific family functioning style appears to be either a necessary or sufficient requirement for developing an eating disorder. As in most psychiatric disorders, various family dysfunctional styles appear to act as nonspecific vulnerability factors and also hamper recovery.

Participation in certain activities in which weight is emphasized may increase the probability of developing anorexia nervosa or another eating disorder. Ballet, gymnastics, modeling, and weight-restricted sports like wrestling or light-weight rowing may lead to preoccupation with body form and unhealthy attempts to control weight. As many of these activities likely select for individuals who are higher in perfectionism, another risk factor for anorexia nervosa, they may be even more likely to contribute to illness onset.

Although it is a common misconception that Western media causes eating disorders, the cultural ideal of thinness, which is certainly perpetuated by the media, may fuel the overvaluation of shape and weight that marks both anorexia nervosa and bulimia nervosa. Indeed, studies in Fiji, where Western media was not available until the 1990s, showed a significant increase in cases of eating disorders following the introduction of Western television shows to the country. Nonetheless, classic anorexia nervosa remains rare, and research has firmly established that media alone does not cause eating disorders.

Bulimia Nervosa

Like anorexia nervosa, there is still much to learn regarding the etiology of bulimia nervosa. This syndrome likely results from the confluence of several factors, as well, many of which overlap with those implicated in the development of anorexia nervosa, but others that differ substantially.

Genetic and Biologic Factors. As in anorexia nervosa, genetics likely play a role in the development of bulimia nervosa, as evidenced by twin and family studies. Individuals with a family history of bulimia nervosa, mood disorder, substance use disorders, or obesity are at higher risk for developing the syndrome. Although GWAS are underway in eating disorders, they have primarily focused on anorexia nervosa and, thus, our knowledge of specific genetic factors implicated in bulimia nervosa remains limited.

Neurobiologic disturbances are also present in individuals with bulimia nervosa and may increase the probability of binge eating. In particular, individuals with the disorder tend to display delayed gastric emptying, enlarged stomach capacity, and reduced secretion of cholecystokinin (CCK), a peptide hormone released by the small intestine that helps to signal satiety during food consumption. Together, disruptions to these neurobiologic processes may put individuals at elevated risk for overeating.

Developmental Factors. The same psychological and social stressors of puberty and adolescence that put individuals at risk for anorexia nervosa also confer risk for bulimia nervosa. Research suggests that hormonal changes during this time, especially shifts in estrogen levels, may be an even greater risk factor in bulimia nervosa than in anorexia nervosa.

Psychological Factors. Unlike individuals with anorexia nervosa, those with bulimia nervosa tend to exhibit high levels of novelty seeking and impulsivity. They also tend to display elevated levels of harm avoidance, negative emotionality, and stress reactivity. Afflicted individuals are more likely than others to experience a comorbid substance use disorder and engage in self-harm, leading to speculation that a subset of individuals with bulimia nervosa may have a propensity toward impulsivity across a range of problematic behaviors. Research findings regarding the possibility of multi-impulsivity as a risk factor for bulimia nervosa remain mixed.

Mood and anxiety disturbances appear to serve as risk factors for bulimia nervosa, as well. In a related vein, research suggests that strong negative emotions may play a role in triggering individual binge episodes in individuals with the disorder, as well, thus acting as maintenance factors in the illness.

Just as the starvation state works to maintain anorexia nervosa, the cycle of binge eating and purging often becomes self-sustaining in bulimia nervosa. Individuals with bulimia nervosa tend to restrict their food intake outside of binge episodes, which puts them at increased risk for episodes of overeating. In turn, after experiencing a binge episode and the resulting compensatory behaviors, individuals often renew their commitment to restrictive eating in an attempt to avoid future overeating episodes. Thus, this cycle tends to become self-perpetuating and works to maintain the disorder.

Environmental and Social Factors. Individuals with bulimia nervosa are likely affected by similar environmental and social stressors as those with anorexia nervosa.

Binge Eating Disorder

Even less is known about the etiology of BED than of anorexia or bulimia nervosa. Twin studies suggest that BED, like other eating disorders, is heritable. Genetic correlations also exist between binge eating and obesity, symptoms of bulimia nervosa, and alcohol dependence. Research thus far has suggested that a history of childhood obesity, mood disorder, and certain negative family dynamics may put individuals at higher risk for developing the illness. In some individuals, dietary restriction appears to play a role in precipitating episodes of binge eating, as in bulimia nervosa. Many individuals with BED, however, seem to experience binge eating outside of the context of dietary restriction. For these individuals, binge episodes may instead be provoked by intense emotions.

DIAGNOSIS AND CLINICAL FEATURES

In DSM-5-TR, the diagnostic criteria for anorexia nervosa, bulimia nervosa, and BED lead to a diagnostic hierarchy so that only one of these diagnoses can be assigned to an individual at a single time. In order of precedence, a diagnosis of anorexia nervosa trumps the other disorders, followed by bulimia nervosa. Finally, rumination disorder cannot be assigned in the presence of any feeding or eating disorder (other than pica). Of note, while these diagnoses may, in general, not occur simultaneously, diagnostic crossover is relatively common, with an individual who previously met criteria for one feeding or eating disorder (e.g., anorexia nervosa) later meeting criteria for a different feeding or eating disorder (e.g., bulimia nervosa). Despite diagnostic crossover and certain shared features, feeding and eating disorders differ substantially from one another in terms of symptoms, behaviors, course, and treatment, as described throughout this chapter.

Anorexia Nervosa

Anorexia nervosa is characterized by three core features, the most salient being restriction of calorie intake resulting in significantly low body weight based on age and height. No specific weight-loss standard defines the illness, so it is important to consider several factors in addition to age and height in determining what constitutes significantly low body weight for an individual. These factors include sex, developmental trajectory, weight history, and current physical health. Nonetheless, drawing from CDC recommendations, DSM-5-TR notes that the usual lower limit of normal body weight in adults is a BMI of 18.5 kg/m^2. Of note, this standard does not apply to children and adolescents who are still undergoing development; for such young people, it is critical to assess their growth trajectory.

Per DSM-5 standards, individuals with anorexia nervosa must demonstrate an intense fear of gaining weight or becoming fat. For individuals who do not articulate or explicitly endorse a fear of weight gain, a diagnosis of anorexia nervosa may still be made in the presence of persistent behaviors that interfere with achieving adequate weight. The behavioral component of this criterion is particularly relevant to children and adolescents, whose age and developmental status may lead to difficulties in verbalizing motivations for engaging in eating disordered behaviors. Additionally, this aspect of the criterion allows individuals who may not endorse fear of fat for cultural reasons to nonetheless obtain a diagnosis of anorexia nervosa.

Finally, anorexia nervosa is marked by disturbances in the experience of body shape or weight. This criterion typically manifests in the way in which an individual with anorexia nervosa perceives their body, believing that their shape is too large or the number on the scale too high despite being at a significantly low weight. Individuals with anorexia nervosa may also place a disproportionate emphasis on thinness in self-schema, such that body shape or weight becomes among the most important aspects in evaluating themselves. Often individuals with this illness do not recognize the severe and dangerous medical risks associated with their current low body weight, even after family, friends, and treatment providers repeatedly emphasize their concern.

Within anorexia nervosa, two subtypes, restricting and binge eating/purging subtype, exist. Individuals with the restricting subtype keep weight off by limiting their daily food intake, often by counting calories, controlling portion size by measuring or weighing food, avoiding specific food items (e.g., cake, red meat) or classes of foods (e.g., fats, desserts), only eating at certain times of the day or a certain amount of time after the last meal, and following other rigid rules that govern eating behaviors. They may also engage in intense and compulsive exercise to lose or maintain weight.

Individuals with the binge eating/purging subtype typically engage in a similar pattern of restrictive eating and may also exercise to keep weight off. However, in addition to these behaviors, individuals who fall under this subtype exhibit recurrent eating binges and/or purging through self-induced vomiting, laxative, or diuretic use. Individuals with these clinical features differ from those with bulimia nervosa because of their low weight status.

Bulimia Nervosa

Bulimia nervosa is marked by repeated episodes of binge eating followed by compensatory behaviors intended to prevent weight gain. Additional details about the definition and assessment of binge eating episodes and compensatory behaviors are provided in the following paragraph. Based on DSM-5-TR criteria, binge eating, and compensatory behaviors must occur on average at least once per week for 3 or more months to warrant a diagnosis of bulimia nervosa. As mentioned in the previous section, unlike individuals with anorexia nervosa, those with bulimia nervosa must be at or above the normal weight during the occurrence of these behaviors. Finally, individuals with bulimia nervosa place undue influence on shape and weight during self-evaluation.

Binge Eating. Central to the diagnosis of bulimia nervosa is the definition of a binge eating episode. In general, according to the DSM-5-TR, an episode of eating is considered a binge when two factors are present: (1) the individual consumes an objectively large amount of food; that is, an amount that most would deem unusually large taking into account the context, and (2) the individual experiences a sense of loss of control, such as feeling that they cannot stop or resist eating at some point during the episode.

While this definition provides a useful framework for thinking about an episode of eating, determining whether an amount of food is objectively large can be difficult. It is useful for the clinician or researcher to ask the patient to describe a typical episode in which eating feels out of control, generate a list of specific foods consumed, and then determine the usual quantity of each food item eaten. Because context may impact whether an amount is considered objectively large, several questions that probe the specific circumstances surrounding the episode should be considered. For example: Was the individual eating alone or with others? If eating with others, how much was everyone else eating? Did the eating occur at a time when overeating might be expected, like at Thanksgiving or a buffet? How much time was spent eating? Did the individual stop eating for an extended period of time during the episode? Table 22–2 provides an overview of questions that may be useful in determining the presence of binge eating and eliciting a typical binge episode.

Although the current DSM-5-TR conceptualization of bulimia nervosa requires clinicians and researchers to assess whether the individual is regularly consuming unusually large amounts of food, as described above, some controversy exists surrounding the importance of the size of the binge. Some experts believe that the amount of food consumed may be less important than the experience of loss of control over eating in making a diagnosis of bulimia nervosa. Indeed, ICD-11 does *not* require that a loss of control eating episode be objectively large for it to be counted as a binge episode. That is, individuals may receive a diagnosis of bulimia nervosa (or BED) if they are having recurrent and frequent subjective and/or objective binge episodes. Research has yet to determine whether individuals who regularly experience loss of control while consuming a normal or small amount of food differ clinically from those who experience objectively large binge episodes, although some studies suggest that binge size does not correlate to psychopathology or impairment. Nevertheless, DSM-5-TR requires that individuals have objectively large binge episodes to qualify for a diagnosis of bulimia nervosa, while ICD-11 has eliminated this requirement.

Table 22–2.
Assessing for Binge Eating

Determining Size of Binge: Is It Objectively Large?

1. Ask about the specific food items typically consumed (e.g., donuts, pizza, chocolate bars)
2. Determine amount of food consumed (e.g., 5 large donuts, 3 slices pizza, 5 fun size chocolate bars)
3. Assess duration of episode, asking about any breaks in eating to determine whether example is better characterized as one or multiple episodes (e.g., 1 hour with no breaks vs. 3 hours with hour-long break in eating)
4. Ask about context:
    a. Was individual alone or with others?
        - If with others, what were they eating at the time?
    b. Did eating occur in a context in which overeating might be expected (e.g., buffet, holiday gathering)?

Probing for Loss of Control

Did you feel like you were unable to stop eating, even if you wanted?

How strong was the drive to continue eating?

If you were interrupted by an external event, would you be able to stop eating?

Did you feel like you could not stop eating until the episode reached its own, natural end point?

Compensatory Behaviors. Individuals with bulimia nervosa engage in inappropriate behaviors to compensate for binge episodes and to control shape and weight. In clinical samples, these individuals most commonly report self-induced vomiting or laxative use. Other compensatory behaviors may include diuretic or enema use, intense exercise, fasting, and medication misuse (e.g., misusing thyroid medication or, in type I diabetes, purposefully restricting insulin use to aid in weight loss). In addition to these behaviors, which must be specifically intended to compensate for episodes of overeating, individuals with bulimia nervosa also tend to restrict or limit their food intake outside of binge episodes. This regular restriction likely plays an important role in the cycle of engaging in binge eating and compensatory behaviors, as described in the previous section on etiology. Specifically, strict rules regarding eating often become impossible to maintain, making the individual more vulnerable to binge eating episodes. Binge episodes, in turn, lead to compensatory behaviors and a renewed desire to restrict food intake to prevent future binge eating episodes, although this logic typically fails.

Binge Eating Disorder

Similar to bulimia nervosa, a diagnosis of BED requires that an individual experiences binge eating episodes at least once per week for 3 or more months. Unlike those with bulimia nervosa, individuals with BED do not engage in regular inappropriate compensatory behaviors. Moreover, in addition to the subjective sense of loss of control that marks binge episodes, behavioral evidence of loss of control must characterize these episodes as evidenced by three or more of the following behavioral criteria: eating much more quickly than usual, continuing eating until uncomfortably full, consuming large quantities of food when not hungry, eating alone due to embarrassment about the amount of food consumed, and feeling depressed, disgusted, and/or very guilty after the eating episode. To warrant a diagnosis of BED, the individual must also report extreme distress about the binge episodes.

Avoidant/Restrictive Food Intake Disorder

ARFID manifests as continual disturbances in eating behavior, which result in clinically significant impairment, such as failure to maintain appropriate weight for age and height, significant nutritional deficiencies, reliance on nasogastric feeding or nutritional supplements to maintain developmentally appropriate weight and/or stable nutritional status, or psychosocial impairment (e.g., inability to eat in public). Individuals with this disorder may exhibit restrictive eating patterns for a variety of reasons, including intense discomfort or dislike of food with certain sensory characteristics (e.g., texture, consistency, smell), fear of eating following an anxiety-provoking, eating-related event (e.g., fear of swallowing after choking or watching someone else choke; fear of eating after an episode of vomiting), or inability to eat normally due to emotional disturbances surrounding eating (e.g., extreme stress surrounding mealtimes due to unpleasant interactions with caregiver). Of note, the reason motivating the restrictive or avoidant food intake must not be weight or shape related, as in anorexia or bulimia nervosa, culturally sanctioned, due to insufficient access to food, or caused by another disorder (e.g., developmental delay).

An 11-year-old K was referred to an eating disorder specialist after her weight fell below the 7th percentile for her age and height. Although K had received treatment for anxiety throughout much of her childhood, she did not manifest worrisome eating until 18 months prior to presentation when she refused to eat during a family vacation because “all the foods tasted weird.” When she returned home, she began to refuse food, citing an intense fear of vomiting. K’s parents were encouraged to wait out the period of change since children often go through phases of picky eating. Yet, K’s eating behaviors became increasingly extreme, and K continued to eat very small amounts. She refused to eat in restaurants and avoided going to friend’s houses or even eating at school, stating that she was less likely to vomit when at home. When she did eat, K would push her food around on the plate, crying when asked to try more. K had been thin throughout childhood, but her weight had hovered around the 25th percentile prior to age 9. When her weight dropped below the 10th percentile and the pediatrician explained the dangerous consequences associated with low weight, K grew tearful and stated that she wanted to gain weight. When asked more about her food restriction, she spoke of an event that occurred years earlier, when she had eaten a meal, grown nauseous, and vomited. She adamantly denied any concern with her appearance, restating her desire to be at a healthy weight.

Pica

Pica refers to the recurrent eating of nonfood, nonnutritive items for at least 1 month by individuals who are at a developmental stage at which this behavior is inappropriate. Individuals who consume nonfood items as part of a culturally sanctioned practice should not receive a diagnosis of pica. Pica most often occurs in individuals with developmental delays or in pregnant individuals, but when a medical or psychiatric condition such as this is present, a diagnosis should only be made if the behavior is so impairing or harmful that it requires separate clinical attention. As mentioned previously, a diagnosis of pica may be assigned in addition to another feeding or eating disorder.

Rumination Disorder

In rumination disorder, individuals repeatedly regurgitate the food that they have consumed before spitting it out, rechewing, or reswallowing it. These behaviors must last at least 1 month for a diagnosis to be made. Although the behavior of rumination may occur in the context of other eating disorders, specifically anorexia or bulimia nervosa, a diagnosis of rumination disorder cannot be given in addition to these illnesses. In other words, to warrant a diagnosis of rumination disorder, the individual must not meet criteria for another feeding or eating disorder (other than pica).

PATHOLOGY AND LABORATORY EXAMINATION

Medical complications are common and often quite serious in both feeding and eating disorders and require close monitoring by the clinical team. Depending on the nature of the disorder, pathophysiologic disturbances may result from starvation and malnutrition, the methods utilized to lose or maintain weight (e.g., restrictive eating, overexercising, self-induced vomiting, laxatives, diet pills, diuretics, or other medication misuse), binge eating, and (in pica) eating of nonfood items. Mortality rates are elevated in both anorexia nervosa and bulimia nervosa due in large part to medical consequences of the disordered behaviors, making medical monitoring particularly important.

When a clinician suspects the presence of a feeding or eating disorder, a full physical examination should be conducted, including height, postvoiding weight in a hospital gown (observing for hidden weights), vital signs (with particular attention to heart rate and orthostatic blood pressure changes), a complete examination of skin, muscle, and subcutaneous fat (noting the degree of starvation), and a neurologic examination (which is, in general, completely normal). Laboratory tests are helpful for assessing the severity of feeding and eating disorders and their medical consequences, although it should be noted that, in many cases, laboratory tests are normal even in the presence of a serious feeding or eating disorder. Abnormal laboratory findings may also be helpful in enhancing the patient's motivation, particularly for individuals who minimize their disorder and its medical implications.

While many of the medical consequences associated with feeding and eating disorders are not imminently dangerous, some require urgent medical evaluation, such as a prolonged QT or QTc (rate corrected) interval on electrocardiogram (ECG) or marked hypokalemia. Medical specialist consultation should be regularly utilized in the management of patients with such abnormalities. Table 22–3 lists the suggested laboratory tests for patients with anorexia nervosa or bulimia nervosa, with judgment regarding the full extent of the workup for individual patients based on weight loss, severity of illness, subtype, and comorbidity. For example, for individuals with anorexia nervosa binge eating/purging type and bulimia nervosa, laboratory tests often include determination of electrolytes and serum amylase, which are more likely to be abnormal in those who purge than in the restricting type of anorexia nervosa. Table 22–4 summarizes common medical consequences of anorexia nervosa, bulimia nervosa, and BED. The following sections provide additional details regarding pathophysiology that may be specific to each eating disorder.

Table 22–3.
Suggested Laboratory Workup for Patients With Anorexia Nervosa and Bulimia Nervosa

For all patients:

- Complete blood count
- Electrolytes
- Blood urea nitrogen, creatinine
- Thyroid-stimulating hormone, free thyroxine
- Total protein and prealbumin
- Fasting glucose
- Amylase if purging occurs
- Serum phosphate
- Electrocardiogram

If underweight or experiencing amenorrhea:

- Bone mineral density (dual-energy x-ray absorptiometry)

Table 22–4.
Common Medical and Physical Complications Associated With Eating Disorders

	Anorexia Nervosa	Bulimia Nervosa	BED
General	▸ Low weight ▸ Loss of body fat ▸ Muscle atrophy ▸ Hypothermia	▸ Weight within normal-overweight/obese range	▸ Weight often in overweight/obese range (with associated complications not listed here)
Skin	▸ Lanugo (fine hair growth on body) ▸ Hair loss or thinning ▸ Carotenemia (yellowing of skin)	▸ Russell sign: Calluses on hands from teeth scraping during self-induced vomiting (not extremely common)	
Cardiovascular	▸ Arrhythmias ▸ Bradycardia ▸ Hypotension ▸ Orthostasis ▸ Prolonged QTc ▸ Peripheral edema	▸ Prolonged QTc ▸ Myocardial toxicity from emetine (ipecac)	
Gastrointestinal	▸ Delayed gastric emptying ▸ Constipation	▸ Gastric distention ▸ Swollen parotid and salivary glands ▸ Elevated serum amylase levels ▸ Erosion of dental enamel, multiple caries	
Electrolyte/Metabolic	▸ Hypokalemia (low potassium) ▸ Hyponatremia (low sodium) ▸ Hypochloremia (low chloride) ▸ Alkalosis ▸ Hypercholesterolemia (high cholesterol) ▸ Hypoglycemia (low blood sugar) ▸ Elevated liver enzymes	▸ Hypokalemia (low potassium) ▸ Hyponatremia (low sodium) ▸ Hypochloremia (low chloride) ▸ Alkalosis	
Endocrine	▸ Low luteinizing hormone ▸ Low follicle-stimulating hormone	▸ Oligomenorrhea or amenorrhea	

	▶ Low estrogen or testosterone ▶ Low thyroxine ▶ Elevated cortisol ▶ Amenorrhea ▶ Decreased bone mineral density (can lead to osteopenia or osteoporosis)
Hematologic	▶ Leukopenia ▶ Anemia

Anorexia Nervosa

Patients with anorexia nervosa may present with certain physiologic abnormalities that are readily apparent even without an extensive evaluation. These may include significantly low body weight, lanugo (soft, fine hair that grows on the body in the starvation state), hair loss or thinning, and carotenemia (yellowing of the skin). Patients may also present with medical complaints that are often confirmed by further examination. They may, for example, report constantly feeling cold and, indeed, their body temperature is often lower than normal, secondary to hypometabolic activity associated with starvation. Reports of weakness may be due in part to muscle atrophy. Many patients report lightheadedness or fainting and are often orthostatic by vital signs, in addition to exhibiting bradycardia. Reports of gastrointestinal discomfort may be related to delayed gastric emptying and constipation, which commonly accompany anorexia nervosa.

Many malnourished patients with anorexia nervosa develop the euthyroid sick syndrome, in which decreased levels of thyroid-stimulating hormone (TSH), total thyroxine (T_4), and total triiodothyronine (T_3) may be seen, free T_4 and free T_3 are usually unchanged, and reverse T_3 (rT_3) is elevated. Generally, these endocrine abnormalities represent energy-conserving consequences of starvation that improve spontaneously with refeeding. They do not require immediate treatment but should be followed to determine if improvement occurs with refeeding.

The hypothalamic–pituitary–gonadal axis is virtually always affected in anorexia nervosa. Low estrogen and progesterone levels are common in women, and low testosterone levels are common in men. Additionally, low levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are seen. Patients with anorexia nervosa have low levels of serum leptin that correlate with low body weight and low body fat, and mediate changes in the hypothalamic–pituitary–gonadal axis.

Related to these abnormalities, bone mineral density is typically low and patients are at risk for osteopenia and osteoporosis, likely due to a combination of low levels of estrogen, high levels of cortisol, and malnutrition. Dual-energy x-ray absorptiometry (DEXA) scans can be helpful in alerting patients to the realistic medical consequences of their disorders. The mechanisms of osteopenia and osteoporosis in anorexia nervosa are more complex than in postmenopausal osteoporosis, and treatments useful in postmenopausal women do not necessarily help in anorexia nervosa. Orally administered estrogen, calcium, and vitamin D supplementation in anorexia nervosa have not been shown to offer benefits in bone mineral density while the patient is still low in weight. While almost all other medical consequences of anorexia nervosa resolve with weight restoration, bone health may not fully recover.

The structural and functional neuropathology of anorexia nervosa is increasingly well documented by magnetic resonance imaging (MRI), computed tomography (CT), fMRI, positron emission tomography (PET), and single photon emission CT (SPECT) scans. Decreases in total brain volume and sulcal complexity and increases in brain ventricular size are usually seen. The neuropathology of anorexia nervosa reverses substantially with refeeding and weight gain. Approximately 40% of typical anorexia nervosa patients score in an abnormal range on two or more neuropsychological tests in standard batteries, suggesting that these patients may have difficulties benefiting from cognitive-behavioral therapies and other psychotherapies in these states. The extent to which long-term improvement in neuropsychological abnormalities may occur in proportion to weight restoration and cessation of binge/purge activity over a prolonged period of stability is not yet clear, and persistent abnormalities in neuropsychological performance following nutritional rehabilitation have been associated with poor prognosis. In usual clinical practice, neuroimaging is not necessary, but in patients with atypical features, especially if other findings suggest that a brain lesion may be present, imaging studies may be of value.

Bulimia Nervosa

Individuals with bulimia nervosa are mainly at risk for medical consequences related to inappropriate compensatory behaviors. Self-induced vomiting, laxative or diuretic misuse, and other compensatory behaviors can cause electrolyte disturbances with serious health risks. Of note, individuals with the binge eating/purging subtype of anorexia nervosa are also at risk for many of the medical sequelae discussed below.

Hypokalemia (low serum potassium), a particularly dangerous electrolyte imbalance that can cause cardiac arrhythmias, commonly occurs in individuals with recurrent vomiting. Thus, potassium should be regularly monitored, especially in individuals with self-reported purging. Likewise, ECGs are recommended to assess for arrhythmias and for prolongation in QT and QTc, which may even occur in individuals without electrolyte abnormalities. Hypomagnesemia (low magnesium) may co-occur with hypokalemia and must also be addressed as it inhibits prolonged normalization of potassium.

Hyponatremia (low serum sodium) also commonly occurs in patients with bulimia nervosa (and often in anorexia nervosa) due either to increased water intake, which dilutes sodium concentration in the blood, or to the development of a syndrome of inappropriate antidiuretic hormone release (SIADH). Individuals with eating disorders may consume excessive amounts of water to aid in appetite suppression and subsequent food restriction or, in the context of treatment that involves weigh-ins, to falsely inflate weight (“water loading”). Hyponatremia increases seizure risk and thus must be addressed quickly. Regardless of the etiology of the hyponatremia, fluid restriction is the treatment of choice. When fluid restriction does not sufficiently improve sodium levels, intranasal arginine vasopressin (ddAVP) should be considered.

As in anorexia nervosa, many individuals with bulimia nervosa may present with dehydration (often due to fluid loss from inappropriate compensatory behaviors). Dehydration may result in tachycardia, orthostatic hypotension, and laboratory abnormalities related to prerenal azotemia, including elevated creatinine and blood urea nitrogen (BUN) levels. Although these issues typically resolve with the normalization of food and fluid intake, intravenous hydration may be necessary in the short term for speedier symptom relief and the reversal of laboratory abnormalities.

Binge Eating Disorder

Obesity and its consequences are the primary health concerns for individuals with BED. Whether individuals with obesity and BED are at greater risk for medical complications than individuals with obesity without an eating disorder remains unclear.

DIFFERENTIAL DIAGNOSIS

Differentiating feeding and eating disorders from other disorders is typically not difficult when a clinician is able to assess current symptoms and behaviors and obtain a full history. Eating disorders in particular have been studied extensively and are therefore more easily separated from other syndromes. Because much less research describing the presentation, course, prognosis, and treatment response of feeding disorders exists at the moment, differential diagnosis for these syndromes may prove more complicated.

Anorexia Nervosa

Because of the prominent physical and behavioral symptoms (i.e., significantly low body weight and restrictive eating) that mark anorexia nervosa, this disorder is typically easy to identify. In certain cases, however, differentiating the disorder from other syndromes may prove more difficult, and clinical judgment may become key in making a diagnosis.

Differential diagnosis may be particularly difficult for individuals who have reached a low body weight but deny or do not articulate fear of gaining weight or becoming fat. By DSM-5-TR criteria, these individuals may still warrant a diagnosis of anorexia nervosa provided that they demonstrate behaviors that persistently interfere with weight gain. Children and individuals from certain cultural backgrounds, in particular, may not acknowledge a fear of becoming fat, but may demonstrate behavioral manifestations of the illness. In these cases, especially in the evaluation of children, collateral information from parents and others may assist in creating a clear picture of the behaviors that the afflicted individual engages in, thus elucidating the diagnosis. Obtaining a full history of the weight loss and any related behaviors often helps to clarify whether the individual should receive a diagnosis of anorexia nervosa, as well.

Throughout the evaluation process, particularly when certain aspects of the illness (such as fear of weight gain) are not readily apparent, clinicians should consider whether a different disorder better explains the low weight status. Medical conditions that may interfere with weight gain, including gastrointestinal problems and thyroid conditions, should be included in the differential diagnosis. When considering these syndromes, however, clinicians should bear in mind that medical sequelae, including gastrointestinal and thyroid abnormalities, are common in eating disorders and their presence does not necessarily exclude a diagnosis of anorexia nervosa.

Individuals with certain psychiatric conditions may also present with weight loss, suppressed appetite, or even fear of eating which can be distinguished from anorexia nervosa. Individuals with psychotic disorders may demonstrate delusions relating to food (e.g., that it has been poisoned) that lead to restricted intake. Mood and anxiety disorders may also include symptoms of weight loss or restrictive eating. For some individuals, a major depressive episode may be accompanied by weight loss and lack of appetite. In certain cases (i.e., when the diagnostic criteria become present), an additional diagnosis of anorexia nervosa may be warranted, but, for many, the weight-related symptoms remain attributable to the episode of depressed mood. Likewise, certain anxiety disorders may lead to weight loss or restrictive behaviors. For example, individuals with a specific phobia of vomit may restrict their eating out of concern that eating could lead to an episode of vomiting, and individuals with

OCD may develop compulsions related to eating behavior (e.g., only taking a bite of food every minute, or eating foods in specific order depending on color). Unless they also begin to manifest other characteristics of anorexia nervosa (including low weight and preoccupation with shape and weight), these individuals should not receive a diagnosis of anorexia nervosa. Clinicians should also consider a diagnosis of ARFID, which is distinct from anorexia nervosa in that psychopathology related to shape and weight concern is absent in this illness.

Under most circumstances, distinguishing anorexia nervosa from bulimia nervosa should be relatively straightforward. The two are differentiated largely on the basis of weight status, with low weight individuals qualifying for a diagnosis of anorexia nervosa regardless of whether or not they engage in episodes of binge eating and compensatory behaviors. The distinction may become more complicated when an individual with recurrent binge eating and compensatory behaviors presents at a body weight that borders on low but is not clearly in the normal or low range (e.g., a BMI of 18.5 kg/m^2). In these cases, obtaining a detailed weight history may help determine if the individual has lost weight in the context of the disordered eating behaviors (making a diagnosis of anorexia nervosa more likely), or if the individual has continued to maintain preillness weight throughout the course of the eating disorder (making a diagnosis of bulimia nervosa more likely).

Individuals who have recently lost a significant amount of weight and demonstrate other characteristics of anorexia nervosa, including fear of weight gain, but who remain within a normal weight range may meet criteria for atypical anorexia nervosa, an example of OSFED in DSM-5. Diagnostically, atypical anorexia nervosa essentially mirrors classic anorexia nervosa, with the exception of the low weight criteria. However, little is known about course, prognosis, or effective intervention strategies for individuals with this diagnosis.

Bulimia Nervosa

When able to obtain a report of current eating behaviors, differentiating bulimia nervosa from other disorders should be relatively straightforward. As discussed earlier in the chapter, perhaps the most challenging aspect inherent to the assessment of bulimia nervosa revolves around determining whether an individual experiences objective binge episodes. This factor is key, as individuals who do not experience objective binge episodes should not, according to DSM-5-TR, receive a diagnosis of bulimia nervosa. Determining whether an individual is experiencing objective binge episodes and compensatory behaviors at the threshold required for a diagnosis of bulimia nervosa (an average of one time per week for 3 or more months) may be particularly important in differentiating bulimia nervosa from other eating disorders. Specifically, individuals who engage in regular compensatory behaviors (e.g., self-induced vomiting, laxative, diuretic, or enema use) but do not report recurrent, objective binge eating episodes may fall under the OSFED category, purging disorder. Alternatively, those who engage in both objective binge eating episodes and compensatory behaviors, but do so less than once per week or for fewer than 3 months should be assigned to the OSFED category, bulimia nervosa of low frequency and/or limited duration. Individuals who report recurrent binge eating without compensatory behaviors should receive a diagnosis of BED. Finally, as mentioned above, bulimia nervosa is distinguished from anorexia nervosa, binge eating/purging type based on weight status.

Some individuals experiencing a major depressive episode may present with episodes of overeating secondary to their mood diagnosis. If, however, their episodes are objectively large, accompanied by a sense of loss of control, followed by compensatory behaviors, and have occurred at or above the required frequency and duration thresholds, an additional diagnosis of bulimia nervosa may be warranted.

Binge Eating Disorder

BED should be relatively easy to recognize based on the patient's self-reported pattern of eating. As described above, BED can be distinguished from bulimia nervosa in that recurrent compensatory behaviors are absent in this diagnosis. Mood should also be assessed as individuals experiencing a major depressive episode may report overeating episodes that could be attributable to the depressive episode or may warrant a separate diagnosis of BED.

Distinguishing BED from the patterns of eating seen in individuals with overweight or obese BMIs without an eating disorder may be particularly difficult. Many individuals presenting above the normal weight range may describe consuming large amounts of food on a regular basis. Only a subset of this population, however, will meet full criteria for BED. In individuals with episodes of overeating who have BMIs consistent with overweight or obesity, it is particularly important to probe for behavioral evidence of lack of control while eating. Individuals with BED typically describe feeling as if they are unable to stop or resist eating, even if interrupted by an external cue, like their phone ringing. Additionally, individuals with BED must demonstrate marked distress over their binge eating.

Avoidant/Restrictive Food Intake Disorder

ARFID should be relatively easy to distinguish from other feeding or eating disorders. While individuals with this disorder may present at low weight and often exhibit eating behaviors that appear quite similar to those seen in anorexia nervosa, individuals with ARFID lack any excessive concern with shape or weight. As mentioned in the discussion of anorexia nervosa, differentiating between these disorders may require particular thought when evaluating children, young adolescents, and individuals from certain cultures who may not explicitly endorse fear of weight gain but who may, nonetheless, demonstrate repeated attempts to avoid weight gain. For this reason, clinicians should not immediately exclude anorexia nervosa from the differential upon hearing an individual deny shape or weight concern. If evidence of attempts to lose or maintain low weight is present, the individual may warrant a diagnosis of anorexia nervosa rather than ARFID.

Importantly, ARFID should not be diagnosed in the presence of another medical or psychiatric condition that explains the restrictive food intake unless the behaviors or symptoms are severe enough to require separate, specialized clinical attention. If eating behaviors are so restrictive that the individual is at risk for medical or nutritional complications, can only maintain health with the assistance of nutritional supplements or nasogastric feeding, or experiences significant psychosocial impairment specifically due to problems with food intake, a diagnosis of ARFID should be made even in the presence of another pre-existing condition. Pre-existing conditions may include medical issues that impact food intake, like gastrointestinal problems that make eating uncomfortable, or psychiatric illnesses, particularly anxiety disorders (e.g., OCD, specific phobia of choking or vomiting), autism spectrum disorders, and developmental delays.

Pica

Pica is the sole feeding or eating disorder that may be diagnosed in addition to any other feeding or eating disorder. For this reason, regular consumption of nonfood items should be assessed even when the presence of anorexia nervosa, bulimia nervosa, BED, ARFID, or rumination disorder has already been established. Like ARFID, pica should not be diagnosed in addition to a pre-existing medical or psychiatric condition unless the feeding or eating behaviors cause substantial impairment to require specialized intervention. Because pica as a behavior often occurs in the context of developmental delays or certain medical conditions (e.g., pregnancy), it is particularly important to determine the severity of the symptoms and whether they necessitate additional care.

Rumination Disorder

Although the behavior of rumination sometimes occurs within an episode of another feeding or eating disorder, particularly anorexia nervosa or bulimia nervosa, rumination disorder as a syndrome cannot be diagnosed according to DSM-5-TR in the presence of anorexia nervosa, bulimia nervosa, BED, or ARFID. Rumination disorder should also be distinguished from the OSFED category, purging disorder, as the behaviors present in these disorders, while similar to some degree, are fundamentally distinct. Rumination refers to the regurgitation of food that has been consumed. While individuals who engage in this behavior may spit out food, this pattern is distinct from purging through self-induced vomiting.

As with ARFID and pica, rumination disorder should not be diagnosed in addition to another disorder unless the behaviors necessitate specialized treatment. Individuals with certain medical conditions, particularly gastrointestinal issues like acid reflux, may report the symptom of rumination, but will usually describe that this behavior occurs involuntarily and that it resolves with treatment of the underlying medical condition. Individuals with developmental delays may also engage in rumination, but only warrant a separate diagnosis if clinically indicated based on symptom severity.

COURSE AND PROGNOSIS

Anorexia Nervosa

Anorexia nervosa typically develops in adolescence, although illness onset may occur at almost any point during the lifespan, with increasingly frequent accounts of it preceding puberty. Most often, the disorder begins when an individual in the normal- or slightly overweight range (commonly an adolescent girl or young woman) starts a diet with the intention of losing a few pounds. The decision to begin dieting usually signifies some level of pre-existing body dissatisfaction and is often spurred by a recent stressor like a breakup, transition into a new school, or a negative comment about shape or weight made by a peer, family member, coach, or dance instructor. For some individuals, initial weight loss is caused not by a diet but rather by an incident entirely outside of the individual’s control, like an acute gastrointestinal condition. Either way, after losing a few pounds, individuals tend to report experiencing positive reinforcement, often in the form of compliments from those around them, that encourage continued weight-loss efforts.

Through this point in the illness trajectory, these individuals may resemble any other teen or adult who loses a few pounds and finds the experience rewarding. However, for individuals vulnerable to developing anorexia nervosa, the illness typically intensifies rather quickly after the initial weight loss. Dietary restriction becomes increasingly severe, with individuals limiting portion size or restricting calories to dangerously low levels, avoiding entire food groups (particularly high-fat foods), and skipping meals. Some individuals also begin to limit fluid intake. Exercise may begin to acquire a compulsive and intense quality, and binge eating and purging (through various means) may emerge. As individuals reach a state of malnourishment and low weight, idiosyncratic ritualistic eating behaviors (e.g., cutting food into small pieces, only eating at set times, concocting strange mixtures of foods) become prevalent. Anxiety and depressive symptoms worsen, preoccupation with body shape and weight intensifies, and individuals tend to become increasingly withdrawn from friends and family.

The precise course of the illness varies substantially, although certain patterns have emerged in the literature. Follow-up studies of patients with anorexia nervosa reveal that, at the time of assessment, approximately 30% to 50% have achieved full recovery, 10% to 20% remain chronically ill, and the remainder have improved but continue to struggle with certain disordered behaviors. The chronically ill group often requires multiple hospitalizations, with a small number of patients being in and out of the hospital for the majority of their lives. Because research on anorexia nervosa tends to examine individuals who have presented for specialized treatment, little is known about the frequency with which individuals experience a brief illness and achieve recovery without eating disorder care.

Of particular note, anorexia nervosa has a mortality rate as high as that associated with any psychiatric illness. Compared to the general population, individuals with the illness are up to six times more likely to die. The majority of deaths are attributable to medical complications of low weight and malnourishment but a smaller, yet significant, proportion of deaths (approximately 1 in 5) are due to suicide.

Although additional research is needed to identify predictors of outcome in anorexia nervosa, studies have found that adolescents with a shorter duration of illness tend to have a better prognosis, emphasizing the importance of early detection and intervention. Studies examining inpatients with anorexia nervosa just prior to and following discharge have also identified certain predictors of post-treatment outcome. In particular, individuals who achieve full weight restoration on an inpatient unit and maintain their weight in the first month after discharge are, perhaps unsurprisingly, more likely to remain at a healthy weight up to a year after treatment. Lower BMI at discharge and weight loss in the first month after treatment, on the other hand, predict poorer long-term outcome. Additionally, individuals who demonstrate an ability to consume a diet that is high in variety and energy density (i.e., a greater concentration of kcal/g) prior to discharge seem to do better after treatment. Finally, a comorbid diagnosis of depression predicts continuing to meet diagnostic criteria for anorexia nervosa decades later.

Bulimia Nervosa

Bulimia nervosa usually develops slightly later than anorexia nervosa, in the late teens or early 20s. Although a substantial portion of individuals report binge eating as their first behavioral symptom of bulimia nervosa, in just under half of all cases restrictive eating and dieting appear to precede the onset of binge eating. Diagnostic crossover from anorexia nervosa to bulimia nervosa is relatively common and, in some cases, restriction may lead to low weight initially, with individuals passing through an episode of anorexia nervosa prior to the development of the bulimia nervosa. In other cases, individuals will remain at normal weight throughout the duration of the dieting. Either way, for those whose illness begins with restrictive eating, this behavior eventually becomes unsustainable, or the individual begins to experience binge episodes. In some cases, the individual may experiment with or even regularly engage in purging before the binge episodes emerge, but more commonly purging starts as a way to compensate for food binges. The cycle of restriction, binge eating, and purging tends to become self-maintaining, as discussed previously.

In general, individuals with bulimia nervosa are more likely than those with anorexia nervosa to attain full or partial recovery, particularly if they have received treatment for the illness. Recent research suggests that, on average, up to 35% of patients with bulimia nervosa who complete an evidence-based treatment achieve full abstinence of core illness symptoms following treatment, and that this rate of abstinence is maintained at follow-up. A larger proportion of patients achieve partial remission. Notably, research finds that bulimia nervosa often goes undetected by health care providers. Several reports suggest an increased mortality risk in this illness. However, study samples typically include a subgroup with a lifetime history of anorexia nervosa who may falsely elevate the mortality risk specifically associated with bulimia nervosa, therefore limiting the interpretation of these data.

Research has yet to identify any clear predictors of outcome in bulimia nervosa. Studies have examined a variety of potential prognostic factors, including duration of illness, age of onset, illness severity, comorbid diagnoses, and personality characteristics, with mixed results. In individuals who receive treatment for bulimia nervosa, studies have found that rapid symptom reduction predicts better outcome.

Binge Eating Disorder

Compared to anorexia nervosa and bulimia nervosa, less is known about the course of BED. In general, the disorder appears to affect an older age group, with patients often presenting for treatment well into adulthood. In most cases, it appears that episodes of binge eating emerge outside of the context of dietary restriction.

Individuals with BED have a much better prognosis than those with anorexia or bulimia nervosa. A substantial number of afflicted individuals appear to experience spontaneous remission without any treatment. One long-term follow-up study found that over 80% of individuals who initially met criteria for BED achieved full recovery 5 years later. The vast majority of individuals in this sample did not receive any treatment over the course of the study. Shorter-term follow-up studies have also found impressive recovery rates, with over 50% of the sample experiencing full remission after just 6 months. Nonetheless, rates of obesity and overweight remain high in individuals with BED, putting these individuals at risk for weight-related health complications.

TREATMENT

Treatment of feeding and eating disorders remains challenging, with empirically supported interventions still lacking for certain populations, like individuals with ARFID, and rates of treatment nonresponse or relapse remaining relatively high even in populations for which evidence-based treatments exist, like bulimia nervosa. Interventions for feeding disorders, in particular, have received very little research attention, although the merging of feeding and eating disorders into one cohesive section in DSM-5 has prompted further investigation into treatment strategies for ARFID, in particular. Although additional research efforts are needed to identify effective interventions for feeding and eating disorders, the sections below will discuss commonly utilized treatments that represent the current understanding of best clinical practices.

Treatment Goals

Although each feeding and eating disorder is substantially different from the others and therefore responds well to different interventions, certain goals of treatment remain the same across the board. As behavioral disorders, one of the primary goals of treatment for any feeding or eating disorder is to disrupt disordered behaviors, specifically, problematic patterns of feeding or eating. For disorders that put individuals at risk for weight problems (i.e., low weight in anorexia nervosa or ARFID), another key goal of treatment is to normalize and stabilize weight. For eating disorders in particular, these two initial goals (normalization of eating behaviors and weight) complement each other, as the normalization of one often promotes the normalization of the other. For example, in anorexia nervosa, weight gain and nutritional rehabilitation often lead to a decrease in ritualistic eating behaviors, and as ritualistic eating behaviors diminish, weight gain and maintenance become more attainable.

A secondary, but often equally important, goal of treatment for eating disorders in particular consists of altering the problematic cognitions, attitudes, and beliefs that may help maintain the disordered behaviors. In anorexia nervosa and bulimia nervosa especially, it is common for many distorted thoughts to decrease in intensity as weight and/or behaviors normalize. In anorexia nervosa, weight stabilization often leads to reduction in obsessive thinking. In bulimia nervosa, breaking the cycle of binge eating, purging, and restriction often allows individuals to recognize the irrational nature of their fears about weight gain. In either case, after disrupting problematic behaviors, additional therapy is typically necessary to work through some of the more deeply ingrained beliefs, such as those that tie weight and shape to self-worth.

Finally, eating disorders have high rates of psychiatric comorbidity, and addressing these problems often becomes important after the eating disorder is stabilized (although, in some cases, the comorbidities may take precedence). For many individuals, certain comorbid symptoms, particularly depressive and anxiety symptoms, substantially diminish following the stabilization of the eating disorder. As the state of starvation is associated with depressed mood and higher levels of anxiety, this is particularly true for individuals with anorexia nervosa who restore their weight. Likewise, as discussed in greater detail below, certain treatments (especially the use of SSRIs and other antidepressants) for bulimia nervosa and BED can simultaneously improve eating disorder symptoms and mood. For other individuals, however, comorbidities require additional, separate treatment even after eating disorder remission.

Level of Care

Important to the discussion of treatment of eating disorders, in particular, is the concept of level of care. Level of care refers to the range of treatment settings that exist (in this case, for eating disorders), from less restrictive options like outpatient therapy, to more intensive interventions like residential or hospital-based treatment programs. In choosing an appropriate option for an individual with an eating disorder, illness severity, including medical status, psychosocial impairment, and the degree of behavioral disturbance, should be considered. Treatment setting should assure safety without being any more restrictive than necessary. Because eating disorders are serious psychiatric conditions that may be associated with medical or psychiatric comorbidity, intensive treatment options often become appropriate or even necessary.

Anorexia Nervosa

The egosyntonic nature of anorexia nervosa (i.e., affected individuals often view some of their symptoms as aspects they wish to continue, or as parts of themselves) can make treatment of this syndrome particularly difficult. Individuals are often ambivalent about recovery. While they may identify certain thoughts or behaviors that they would like to resolve (e.g., distressing obsessive thoughts about food, shape, or weight; objective or subjective binge eating episodes; weakness and fatigue), or certain areas of their life that might improve without the eating disorder (e.g., relationships, concentration), they typically remain very afraid of and resistant to the idea of gaining weight. This ambivalence can make engaging patients in treatment particularly challenging. Therefore, an initial goal of treatment should be for the clinician to establish a positive, supportive relationship with the patient and to begin to involve him or her in treatment planning. Psychoeducation, including a full discussion of the medical risks associated with low weight, often plays an important role in motivating the patient, particularly in the initial phases of treatment.

Because of the complex nature of the illness and the high frequency of serious medical and psychiatric comorbidities, individuals with anorexia nervosa typically require a treatment team, or a group of clinicians with different specializations who work together to help the individual make progress. This team may deliver care on an outpatient basis or in a more structured setting and typically consists of a group of multidisciplinary clinicians, including a therapist and/or a psychiatrist, nutritionist, and general medical doctor. In more structured settings, the team often includes additional members, including nursing staff, mental health aids, recreational or occupational therapists, and social workers. For children and adolescents, in particular, parents or other family members may take on an active role in refeeding and weight restoration. Each member plays a different specialized role, but it is imperative that the team regularly communicates regarding treatment goals, progress, and plan.

For adults with anorexia nervosa, no particular treatment has emerged as clearly superior based on empirical studies. For adolescents and children with anorexia nervosa, certain treatments, particularly family-based therapies (discussed below), have demonstrated efficacy in research trials. Despite the limited research support for existing interventions, a variety of treatment types and modalities can promote recovery for individuals with the illness.

Nutritional Rehabilitation and Weight Restoration. Nutritional rehabilitation and weight restoration are primary treatment goals that may be achieved at any level of care, although inpatient hospitalization typically allows for the most efficient refeeding process because of the close supervision with medical monitoring that is available. The following section will discuss weight restoration and nutritional rehabilitation in a structured setting, although many of these principles may be applied to less structured treatment settings, as well.

Structured treatments are indicated for individuals who have not achieved weight gain in outpatient settings, or whose behaviors or symptoms are severe enough to require a higher level of monitoring or care than is possible on an outpatient basis. Individuals presenting with serious medical complications or suicidal ideation or behavior are typically candidates for inpatient treatment. Several options that vary in intensity exist under the umbrella of structured treatment, but all share the primary goal of weight restoration. Most structured settings employ behavioral protocols aimed at normalizing weight through calorie prescriptions, meal plans, structured and supportive meals, disruption of compensatory behaviors (including purging and exercise), and expectations of regular weight gain. A treatment team also provides a range of individual and group therapies, some of which are discussed later in this section.

A privilege or level system is often employed, such that individuals enter the program at the lowest and most restrictive level but can increase their level and subsequently gain privileges and autonomy as they progress through treatment. Prorecovery behaviors (e.g., eating 100% of food on the meal plan, abstaining from compensatory behaviors, meeting weight gain goals) are rewarded with positive reinforcements, which may mean gaining access to different group activities, receiving less monitoring and supervision, taking a more active role in meal planning, etc. Behaviors that cater to the eating disorder (e.g., restricting food intake, purging or exercising, failing to meet weight gain expectations) are met with negative reinforcements, or a reduction in privileges and an increase in supervision. For individuals who continuously fail to gain weight, activity is restricted to decrease calorie expenditure, and bed rest may be employed.

In most structured facilities, calorie prescription starts between 1,500 and 1,800 kcal/day (and emerging evidence suggests that higher rates, around 2,000 kcal/day, are safe and more efficacious) consumed across three to four supervised meals and snacks. Macronutrient content is also prescribed so that patients receive the necessary daily requirements. Because this diet represents an increase in food intake compared to pretreatment consumption for almost all patients with anorexia nervosa, medical status should be monitored closely for signs of refeeding syndrome, a rare but potentially fatal medical complication that involves fluid, electrolyte, and mineral shifts in the body (see Table 22–5 for common signs of this syndrome). Despite the need for careful medical monitoring during this time, a diet of 1,500 to 1,800 kcal/day has been shown to be a safe starting point for patients with anorexia nervosa across various research studies. Additionally, due to the medical complications associated with low weight and starvation, it is typically viewed as safer and more ethical to increase calories (and therefore, weight) relatively quickly.

Most programs will maintain calories around 1,500 to 1,800 for several days until the patient is clearly medically stable. At this point, calories are typically increased in a predetermined sequence, often by several hundred calories every other day, until a diet consisting of approximately 3,500 to 4,000 kcal/day is achieved. To meet these calorie needs, patients may consume high-calorie nutritional supplements, like Ensure, as part of the meal plan. For individuals who refuse to consume solid foods or nutritional supplements, some facilities utilize nasogastric feeding (i.e., tube feeding) to achieve weight gain, although this option is generally viewed as less ideal as it is important for patients to practice normal eating as part of the recovery process.

While calorie prescriptions on structured units are typically quite high, it is important to consider that in order to gain 1 lb, an individual must exceed his or her energy requirements by roughly 3,500 kcal. Thus, the calorie prescriptions described above typically result in gaining between 2 to 5 lb per week. Goal weights are determined at the start of the treatment, but vary across facilities and are often impacted by insurance coverage. Generally speaking, for an individual to achieve full weight restoration, BMI should be increased to greater than 18.5 kg/m^2 or 85% IBW, and most clinicians agree that a BMI above 20 kg/m^2 or 90% IBW is healthier and more likely to prevent relapse. For children or adolescents, goal weight should be determined based on pediatric growth curves and, for adults, it is often useful to consider preillness weight history to determine if a goal weight substantially higher than a BMI of 18.5 kg/m^2 or 85% IBW should be recommended. Despite these clinical goals, health insurance companies may limit reimbursement, covering weight restoration to weights or BMI ranges that are often below ideal.

Table 22–5.
Signs of Refeeding Syndrome

Lab Abnormalities
Hypophosphatemia
Hypokalemia
Hypomagnesemia
Thiamine deficiency
Glucose intolerance

EKG Abnormalities
Dysrhythmias
Torsades de pointes

Physical Symptoms
Edema
Respiratory difficulty
Muscle pain and weakness
Gastrointestinal disturbances (e.g., constipation, diarrhea)

While weight restoration often resolves many of the depressive and anxiety symptoms associated with the starvation state, additional therapy is almost always indicated after weight has been normalized to prevent relapse, continue to focus on disordered thoughts and behaviors and work through any underlying issues or comorbidities. Some structured treatments utilize stepped care systems, in which individuals can transition from higher levels of care (e.g., inpatient or residential) to lower levels of care (e.g., day treatment, evening program, outpatient) within the same system as they progress through treatment. Other programs depend on case managers or other staff members to set up discharge plans that aim to help individuals maintain treatment gains. Throughout structured treatment and after, a variety of psychotherapy options are available.

Psychotherapy. Several psychotherapies have been evaluated for the treatment of anorexia nervosa, both in structured and unstructured settings. For adults, several therapies are regularly used and recommended for clinical management of the illness. Some consistent research findings regarding modest but significant clinical improvements following these therapies support their use; however, upon careful inspection it appears that no particular therapy is better than the others for the treatment of adults with anorexia nervosa, and none is dramatically superior to treatment as usual.

Perhaps the most extensively studied and utilized treatment for anorexia nervosa is cognitive-behavioral therapy (CBT), which often focuses on helping the individual alter disordered behaviors regarding eating, exercise, and other compensatory behaviors, challenge related distorted thoughts, and identify negative core beliefs. Interpersonal psychotherapy (IPT), which focuses on dysfunction in interpersonal relationships, social roles, and communication, is also often used for the treatment of anorexia nervosa with similar outcome to that of CBT. Treatment that targets maladaptive habits in anorexia nervosa has also garnered initial support. Research has also begun to explore third-wave cognitive behavioral therapy approaches such as acceptance and commitment therapy (ACT), which aims to increase psychological flexibility or the ability to live life according to one’s personal values despite psychological distress. The effect of these therapies on outcomes in anorexia nervosa requires additional study. While most psychotherapies for anorexia nervosa that have been empirically evaluated are rooted in cognitive-behavioral principles, focal psychodynamic therapy has been examined in a controlled trial, and again, seems to fare similarly to other therapies.

For children and adolescents with anorexia nervosa, family-based therapies have garnered substantial research support. As their name suggests, these therapies focus on involving parents and other family members in the treatment of the eating disorder. The "Maudsley Method," in particular, has demonstrated effectiveness across a number of research studies. In this approach, parents take on the responsibility of refeeding their child with the therapist's coaching and support. The parental role often mirrors that of staff members on an inpatient unit who are helping a patient achieve weight restoration. Parents help to enforce meal plans, caloric intake, and weight gain by providing empathic but firm support and supervision, particularly during mealtimes. As the child progresses through treatment, control over eating is ultimately transitioned back to them. The final stage of treatment focuses on ways in which the eating disorder has impacted the child or adolescent's development, with the goal of ultimately establishing a healthy adolescent identity. More recently, a related therapy, parent-focused treatment, has emerged. Parent-focused treatment is nearly identical to family-based therapy, but parents meet alone with a clinician, which may improve access to and acceptability of care. Preliminary studies support the efficacy of parent-focused treatment. It is also worth noting that a Maudsley anorexia treatment for adults (MANTRA), which targets interpersonal factors among other things, has recently been developed and shows promise.

Psychopharmacology. Although many medications have been studied for the treatment of anorexia nervosa, empirical support for most is lacking. The treatment of anorexia nervosa using antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs), has received significant research attention. Nonetheless, studies have consistently demonstrated that, when compared to placebo, antidepressants do not significantly aid in weight gain, alter eating pathology, or reduce depressive or anxiety symptoms in underweight individuals with anorexia nervosa. Rather, weight restoration itself has been shown to reduce symptoms of depression and anxiety. A small number of studies have also examined the efficacy of SSRIs after weight restoration and similarly found no significant impact on relapse prevention or psychological outcome. Despite these findings, some individuals whose depressive symptoms do not diminish with weight restoration may benefit from antidepressant treatment following weight restoration.

Atypical antipsychotic medications have also been studied in the treatment of anorexia nervosa. In normal-weight individuals without eating pathology, atypical antipsychotic medication often results in extreme and unwanted weight gain, although the precise mechanism of this change remains unknown. In patients with anorexia nervosa, one atypical antipsychotic, olanzapine, has demonstrated efficacy in promoting weight gain with few side effects at a dose of 5 to 10 mg/day. Of note, treatment studies of olanzapine in patients with anorexia nervosa have demonstrated much more modest weight gains than are observed in noneating disorder psychotic patients taking the medication. Additionally, olanzapine does not appear to improve psychological symptoms of anorexia nervosa.

Ms. T, a 20-year-old woman, was admitted to an inpatient eating disorder unit at a height of 5 ft 7 in and a weight of 105 lb (BMI: 16.4 kg/m^2; 75% IBW). At the time of her admission, Ms. T described a history of disordered eating starting 2 years earlier, soon after entering college. The transition to college was stressful for Ms. T who felt homesick and struggled to make friends. She ran cross-country throughout high school, maintaining a BMI of around 19.5 kg/m^2 until college, when, in the context of discontinuing her exercise regimen and adjusting to buffet meals in the cafeteria, she gained approximately 10 lb. Ms. T experienced significant distress surrounding her weight gain and began eliminating snacks and desserts from her diet, successfully losing 5 lb. She enjoyed compliments from acquaintances regarding her weight loss and decided to resume regular exercise, eventually increasing her running to 5 to 10 miles daily. Her exercise quickly began to feel driven, and she noted feelings of intense guilt and increased dietary restriction when she missed a day. She also began to skip meals and avoided eating in the cafeteria. Within 2 months, she lost 20 lb (BMI: 18.0 kg/m^2; 82% IBW), her menstrual periods became irregular, and she struggled with low mood. She became intensely afraid of becoming fat and weighed herself twice daily to ensure that her weight had not increased. At this point, Ms. T was subsisting on two meals per day totaling approximately 500 to 700 kcal and consisting of foods that she deemed “safe” (e.g., fat-free Greek yogurt, grilled chicken, vegetables). She ate at a set time each day and weighed and measured each food item before consuming it, keeping a detailed food log. When her parents became aware of the eating disorder, Ms. T began to see a therapist, nutritionist, and medical doctor on an outpatient basis. She increased her weight by several pounds and her exercise and food rituals loosened. However, the following year, an ankle injury prevented her from running and Ms. T began to restrict her food intake more severely, losing to a BMI of 16.4 kg/m^2 (75% IBW). Subsequently, her treatment team recommended inpatient care with the goal of restoring her weight and becoming reacquainted with healthy eating habits.

Bulimia Nervosa

Interventions with strong empirical support exist for bulimia nervosa, although there is still substantial room for improvement as a significant portion of individuals continues to experience symptoms after receiving evidence-based treatment. Many individuals with bulimia nervosa respond well to and remain medically stable during the course of established outpatient treatments and, thus, inpatient care is indicated far less often than it is for anorexia nervosa.

Psychotherapy. Several psychotherapy approaches for bulimia nervosa have received research attention, with CBT emerging as the treatment of choice for the illness. CBT has demonstrated efficacy in both individual and group formats, with 30% to 50% of individuals reporting symptom abstinence following treatment and a higher percentage reporting symptom reduction. CBT for bulimia nervosa has also been adapted into pure and guided self-help formats, with both showing greater effectiveness than a waitlist control condition (although research has yet to determine how CBT self-help formats compare to the standard face-to-face modality).

CBT for bulimia nervosa consists of several phases, each meant to disrupt problematic behaviors (e.g., binge eating, purging, restricting) and identify and restructure distorted thoughts and beliefs that may be maintaining the unhealthy behaviors (e.g., “Eating sugary foods will make me fat"). In general, disordered behaviors are tackled first and, once they have improved, cognitive distortions become the focus of treatment. The initial phase of treatment often involves psychoeducation and working with the patient to increase the regularity of eating and resist urges to binge or purge. Self-monitoring and recording are key strategies in CBT and may rely on pen and paper or utilize web-based applications, which have become increasingly accessible and seemingly useful. In addition to self-monitoring and recording, patients receive various homework assignments to help identify and alter unhelpful behaviors and dysfunctional attitudes and beliefs. Patients are also taught to identify stressors or triggers and to employ more adaptive coping strategies. Finally, after symptoms have abated, relapse prevention strategies are used to reduce the likelihood of a return of symptoms by anticipating and preparing for stressful situations and setbacks likely to be encountered in the future.

In addition to CBT, several other psychotherapies have emerged as helpful in the treatment of bulimia nervosa. IPT, in particular, has been shown to reduce binge eating and purging, although research suggests that CBT does so more rapidly. Specifically, one study found that, at the end of treatment, a significantly higher percentage of individuals in the CBT group experienced symptom abstinence as compared to the IPT group (45% in CBT vs. 8% in IPT). However, individuals in the IPT group make additional gains after treatment and, 1 year later, essentially catch up to the CBT group in terms of rate of symptom abstinence (40% in CBT vs. 27% in IPT). As in anorexia nervosa, IPT for patients with bulimia nervosa focuses on dysfunctional interpersonal relationships.

While they have received less research attention, dialectical behavioral therapy (DBT), ACT, and integrative cognitive-affective therapy (ICAT) also show promise for the treatment of bulimia nervosa. Each draws from principles of CBT, but differs in certain ways. DBT focuses on helping patients develop mindfulness, emotion regulation, and distress tolerance in an attempt to regulate distressing emotions that may contribute to maladaptive eating behaviors. As described above, ACT helps individuals develop psychological flexibility by identifying personal values and learning skills for accepting uncomfortable internal experiences (e.g., anxiety) in the service of committing to living a values-driven life. ICAT, in addition to focusing on distorted cognitions and problematic behaviors as in CBT, emphasizes the role of dysfunctional interpersonal interactions on the eating disorder. Additional research is needed to further clarify the efficacy of these therapies in the treatment of bulimia nervosa.

Psychopharmacology. Research has identified several medications that effectively reduce symptoms in many patients with bulimia nervosa, particularly when administered in conjunction with evidence-based psychotherapy. Notably, research suggests that a course of drug therapy alone is inferior to a course of CBT alone, but some studies suggest that a combination of the two interventions may be more helpful than either alone. Thus, medication as the sole therapy for bulimia nervosa is typically not the first choice recommendation, but medication as an adjunctive treatment for bulimia nervosa has a strong evidence base.

Antidepressants in particular have amassed substantial research support for the treatment of bulimia nervosa and, of note, are equally effective for patients with and without depressive symptoms. Although several antidepressants appear to significantly reduce binge eating and purging, the SSRI fluoxetine has been studied the most extensively and is viewed as the medication of choice for this illness. Although the medication is traditionally prescribed at a dose of 20 to 40 mg/day for the treatment of depressive disorders, studies have found that a higher dose (60 mg/day) is more effective in disrupting binge eating and purging. Even at this higher dose, fluoxetine has fewer side effects than some of the other medications described below that have demonstrated efficacy in treating bulimia nervosa. Research has yet to determine the optimal length of fluoxetine treatment for bulimia nervosa as most trials have been relatively short.

Tricyclic antidepressant medications (TCAs), monoamine oxidase inhibitors (MAOIs), and atypical antiepileptic agents such as topiramate have also demonstrated efficacy in randomized controlled trials of bulimia nervosa. TCAs and MAOIs, however, are not viewed as a first-line treatment due to significant side effects and the risk of fatal overdose. Across several studies, topiramate has resulted in significant weight loss in patients with bulimia nervosa, a complicated side effect for an eating disorder patient that should be carefully considered prior to treatment initiation. Finally, bupropion is contraindicated for bulimia nervosa due to concerns regarding an increased risk for seizures in patients who are actively purging.

Binge Eating Disorder

Because both disorders are marked by recurrent episodes of binge eating, much of the treatment research for BED has focused on interventions that are known to effectively treat bulimia nervosa. However, the substantial portion of patients with BED who are overweight or have obesity may require additional treatment to achieve a healthier body weight, although clinicians tend to agree that binge eating behavior should be addressed before weight reduction is attempted. Additional studies examining interventions for BED are currently underway.

Psychotherapy. As in bulimia nervosa, CBT has emerged as a highly effective treatment for BED with over 50% of individuals attaining abstinence from binge eating following treatment. CBT for BED is structured quite similarly to CBT for bulimia nervosa, without the focus on inappropriate compensatory behaviors. Despite its efficacy in reducing binge eating in BED, studies have found that CBT does not effectively result in weight loss for individuals with overweight or obesity.

IPT may be even more useful for BED than it is for bulimia nervosa. In fact, research examining IPT versus CBT for BED suggests that the two interventions may be equally efficacious both at the end of treatment and in follow-up. DBT, too, may be effective in the treatment of BED, but additional studies are needed to determine this therapy’s impact on this population.

Psychopharmacology. Many of the medications that are useful for bulimia nervosa also reduce binge eating in BED, although long-term studies have yet to examine whether these treatment gains persist over time. Specifically, SSRIs and TCAs compare favorably to placebo in eliminating binge eating but do not aid in weight loss. Because it both reduces binge eating and causes weight loss, topiramate appears to serve as an effective treatment for BED, as well. Weight loss medications have not been extensively studied in the treatment of BED, although one, orlistat, seems to promote weight loss but does not reduce binge eating. Other appetite-suppressing and weight-reducing medications have been considered for this population, including stimulants. Most recently, lisdexamfetamine has been approved by the FDA for short-term treatment of BED.

Weight Loss Treatment. Treatment of the obesity associated with BED requires both nutritional modification with calorie reduction and an increase in exercise. For severe obesity, especially class III (BMI ≥40 kg/m^2), medical supervision and, possibly, bariatric surgery may be recommended.

ARFID

Prior to the inclusion of ARFID in the Feeding and Eating Disorders section of DSM-5, very little research had investigated effective treatments for this disorder. Since the publication of DSM-5, preliminary treatment research has been conducted, primarily in children and adolescents. Overall, these initial studies suggest that CBT shows promise for children, adolescents, and adults with ARFID. Some patients with ARFID, similar to those with anorexia nervosa, may be medically compromised and require a higher level of care than outpatient treatment to achieve nutritional rehabilitation and/or weight restoration. In other cases, when medical sequelae are less severe, an outpatient medical team can appropriately manage the needs of the patient. There are not yet consensus guidelines regarding the medical management of patients with ARFID, but many of the practices described above for patients with anorexia nervosa can be effectively used for this population.

Pica and Rumination Disorder

Very little research has investigated effective treatments for pica or rumination disorder. Behavioral strategies that have been identified as useful for other disturbances of eating behavior are often "borrowed" for treatments that aim to normalize behaviors in individuals with these disorders.

Sleep Disorders

Amir Sharafkhaneh, M.D., Ph.D., Habibolah Khazaie, M.D., and Max Hirshkowitz, Ph.D.

OVERVIEW

To understand sleep and its disorders, it helps to begin with sleep's three basic characteristics. (1) Sleep is a process required for proper brain function. Failure to sleep impairs thought processes, mood regulation, and a host of normal physiologic functions. (2) Sleep is not a single process; there are several distinct types of sleep. These different types of sleep differ both qualitatively and quantitatively. Each type of sleep has unique characteristics, functional importance, and regulatory mechanisms. Selectively depriving one particular type of sleep produces compensatory rebound when an individual is allowed to sleep *ad lib*. (3) Sleep is not a passive process; sleep can be associated with a high degree of brain activation and metabolism.

Several physiologic mechanisms regulate sleep, and when these systems go awry, sleep disorders occur. Initial interest in sleep disorders emanated from psychiatrists, psychologists, and neurologists. During the past five decades, medical research expanded sleep medicine into a multidisciplinary field. Research confirming sleep-disordered breathing's medical consequences attracted many pulmonary, internal medicine specialists, and cardiologists to the field. Perioperative risks associated with patients with sleep-disordered breathing attracted the attention of anesthesiologists, and treatment options for breathing disorders now involve surgeons and dentists. Sleep–wake cycle related endocrinology and circadian rhythm research migrated from the laboratory bench to the bedside. Nonetheless, the seriousness of sleep disorders remains poorly recognized by the general public and many clinical practitioners. Progress, however, is being made. *Sleep Medicine* is now a recognized medical specialty, and ACGME accredited Sleep Medicine Fellowship Training programs exist.

Some sleep disorders are both dangerous and their consequences can be costly. Hypersomnolence is a serious, potentially life-threatening condition affecting not only the sleepy individual but also their family, coworkers, and society in general. In fact, sleep-related motor vehicle accidents represent a major public safety concern, with some states enacting criminal statutes to deter sleepy driving. Investigations link many major industrial catastrophes to sleepiness. Research shows that sleep-disordered breathing contributes to hypertension, heart failure, and stroke. Sleep disorders' direct cost per annum in the United States is estimated at 16 billion dollars, with indirect costs ranging upward to more than 100 billion dollars.

SLEEP DISORDERS CLASSIFICATIONS

Three different nosologies provide classification systems for sleep disorders: (1) the Diagnostic and Statistical Manual of Mental Disorders (DSM), (2) the International Classification of Sleep Disorders (ICSD), and the International Classification of Diseases (ICD).

The American Psychiatric Association's DSM-5 and its text revision (DSM-5-TR) represents the standard diagnostic system used by most physicians who are not Sleep Medicine Specialists. Sleep Medicine specialists often prefer using the ICSD-3 (which is cross-referenced to the required DSM-5-TR coding). The World Health Organization's ICD-10 is not as popular (in the United States). The three systems' organizational schemas differ. Some lump multiple nosologic entities into a single diagnostic classification while others split disorders, providing separate designations. In the present chapter, we will use DSM-5-TR as an organizational guideline because (1) it represents a diagnostic standard, (2) its coding system is widely used, and (3) it is the parsimonious classification system describing essential sleep–wake disorders. ICSD-3 is more comprehensive; however, diagnostic differentiation sometimes resembles research diagnostic criteria rather than clinical practice criteria. Where appropriate, ICSD-3 diagnostic entities will be discussed as clinical subtypes. ICSD-3 is the direct descendent of the first comprehensive sleep disorders nosology commissioned in 1979 by the Association of Sleep Disorders Centers (now the American Academy of Sleep Medicine) (see Table 23–1). Diagnostic criteria for DSM-5-TR and ICSD-3 are quite similar (and sometimes identical) for the major sleep disorders. Finally, we chose DSM-5-TR to organize this chapter because, after all, this is the Comprehensive Textbook of Psychiatry.

INSOMNIA DISORDER

Previously, DSM-IV defined insomnia as difficulty initiating sleep, maintaining sleep, or nonrestorative sleep for 1 month or more. ***The overall conceptualization of insomnia has changed dramatically, beginning with the dissatisfaction with sleep quantity or quality serving as the primary element.*** Three other paradigm shifts in thinking also include the following. First, nonrestorative sleep and its consequent sleepiness no longer represent a key feature for insomnia. Nonrestorative sleep is now considered an attribute of hypersomnolence. Second, whereas insomnia was previously considered a symptom secondary to some other underlying problem, it is now recognized as a possible independent condition. Third, the hitherto insomnias considered secondary are now considered comorbid. In the past, practitioners were admonished to treat insomnia's cause rather than the symptoms. There was an implicit notion that by doing so, the sleep problems would improve. Clinical experience suggested otherwise. Consequently, current therapeutics favor providing relief and managing symptoms. To some extent, this change in thinking parallels our getting away from monotherapy. In the past, it was argued that if insomnia was related to depression, treating the insomnia would mask the depression and thereby interfere with antidepressant treatment regimens. This does not appear to happen.

Diagnostic Criteria

Insomnia should be evaluated according to eight criteria. DSM-5-TR sets forth these as follows: (1) how it adversely affects sleep; (2) how it influences subsequent wakefulness; (3) its frequency; (4) its chronicity; (5) whether it occurs in conjunction with some other sleep disorders, (6) medication or substance use, or (7) some other psychiatric, neurologic, or medical conditions. Also, (8) the sleep difficulty must occur notwithstanding an adequate opportunity to sleep.

Table 23–1.
Outline of the International Classification of Sleep Disorders, Third Edition

I. Insomnia
    A. Chronic Insomnia Disorder
    B. Short-Term Insomnia Disorder
    C. Other Insomnia Disorder
    D. Isolate Symptoms and Normal Variants
        1. Excessive Time in Bed
        2. Short Sleeper

II. Sleep-Related Breathing Disorders
    A. Obstructive Sleep Apnea Disorders
        1. Obstructive Sleep Apnea, Adult
        2. Obstructive Sleep Apnea Disorder, Pediatric
    B. Central Sleep Apnea Syndromes
        1. Central Sleep Apnea with Cheyne–Stokes Breathing
        2. Central Apnea Due to a Medical Disorder without Cheyne–Stokes Breathing
        3. Central Sleep Apnea Due to High-Altitude Periodic Breathing
        4. Central Sleep Apnea Due to a Medication or Substance
        5. Primary Central Sleep Apnea
        6. Primary Central Sleep Apnea of Infancy
        7. Primary Central Sleep Apnea of Prematurity
        8. Treatment-Emergent Central Sleep Apnea
    C. Sleep-Related Hypoventilation Disorders
        1. Obesity Hypoventilation Syndrome
        2. Congenital Central Alveolar Hypoventilation Syndrome
        3. Late-Onset Central Hypoventilation and Hypothalamic Dysfunction
        4. Idiopathic Central Alveolar Hypoventilation
        5. Sleep-Related Hypoventilation Due to a Medication of Substance
        6. Sleep-Related Hypoventilation Due to a Medical Disorder
    D. Sleep-Related Hypoxemia Disorder
        1. Sleep-Related Hypoxemia
    E. Isolated Symptoms and Normal Variants
        1. Snoring
        2. Catathrenia

III. Central Disorders of Hypersomnolence

  - A. Narcolepsy Type 1
  - B. Narcolepsy Type 2
  - C. Idiopathic Hypersomnia
  - D. Kleine–Levin Syndrome
  - E. Hypersomnia Due to a Medical Disorder
  - F. Hypersomnia Due to a Medication or Substance
  - G. Hypersomnia Associated with a Psychiatric Disorder
  - H. Insufficient Sleep Syndrome
  - I. Isolated Symptoms and Normal Variants
    - 1. Long Sleeper
- IV. Circadian Rhythm Sleep–Wake Disorders
  - A. Delayed Sleep–Wake Phase Disorder
  - B. Advanced Sleep–Wake Phase Disorder
  - C. Irregular Sleep–Wake Rhythm Disorder
  - D. Non–24-Hour Sleep–Wake Rhythm Disorder
  - E. Shift Work Disorder
  - F. Jet Lag Disorder
  - G. Circadian Sleep–Wake Disorder Not Otherwise Specified
- V. Parasomnias
  - A. NREM-Related Parasomnias
    - 1. Confusional Arousals
    - 2. Sleepwalking
    - 3. Sleep Terrors
    - 4. Sleep-Related Eating Disorder
  - B. REM-Related Parasomnias
    - 1. REM sleep behavior disorder
    - 2. Recurrent Isolated Sleep Paralysis
    - 3. Nightmare Disorder
  - C. Other Parasomnias
    - 1. Exploding Head Syndrome
    - 2. Sleep-Related Hallucinations
    - 3. Sleep Enuresis
    - 4. Parasomnia Due to Medical Disorder
    - 5. Parasomnia Due to a Medication or Substance
    - 6. Parasomnia, Unspecified

        7. Isolated Symptoms and Normal Variants
            a. Sleep Talking
- VI. Sleep-Related Movement Disorders
    - A. Restless Legs Syndrome
    - B. Periodic Limb Movement Disorder
    - C. Sleep-Related Leg Cramps
    - D. Sleep-Related Bruxism
    - E. Sleep-Related Rhythmic Movement Disorder
    - F. Benign Sleep Myoclonus of Infancy
    - G. Propriospinal Myoclonus at Sleep Onset
    - H. Sleep-Related Movement Disorder Due to Medical Disorder
    - I. Sleep-Related Movement Disorder Due to a Medication or Substance
    - J. Sleep-Related Movement Disorder, Unspecified
    - K. Isolated Symptoms and Normal Variants
        - 1. Excessive Fragmentary Myoclonus
        - 2. Hypnagogic Foot Tremor and Alternating Leg Muscle Activation
        - 3. Sleep Starts (Hypnic Jerks)
- VII. Other Sleep Disorder

From American Academy of Sleep Medicine. *International Classification of Sleep Disorders*. 3rd ed. American Academy of Sleep Medicine; 2014.

The primary criteria descriptively relate to how insomnia affects sleep. Specifically, one or more of the following must be present: (a) difficulty initiating sleep, (b) difficulty maintaining sleep, or (c) early-morning awakening with an inability to resume sleep. In the case of children, insomnia can manifest as resistance to the caregiver’s designation of bedtime and/or difficulty sleeping without caregiver intervention. The influences on subsequent wakefulness in DSM-5-TR include “significant distress or impairment of social, occupational, educational, academic, behavioral, or other important areas of functioning.” ICSD-3 also considers fatigue; malaise; attention, concentration, or memory impairment; mood disturbance; irritability; behavioral problems (especially in children), including hyperactivity, impulsivity, or aggression; reduced motivation, energy, or initiative; and error or accident proneness.

Frequency and chronicity criteria stipulate sleep disturbance (with associated symptoms) three times per week (or more) for 3 months or longer. Based on DSM-5-TR, the insomnia must not be better explained by another sleep, psychiatric, neurologic, or medical disorder; must not be attributable to a medication or substance use; and must persist when an adequate opportunity for sleep occurs.

When the diagnosis of Insomnia Disorder is made, the clinician should also specify if there are comorbid conditions (be they sleep disorder, psychiatric, neurologic, or medical) and whether the insomnia occurs episodically (symptoms last one or more months but less than 3 months), persistently (3 months or more), or recurrently (two, or more, episodes in a 12-month period).

Insomnia Subtypes

Neither DSM-5-TR nor ICSD-3 formalizes diagnostic criteria for clinical and pathophysiologic insomnia subtypes. Nonetheless, ICSD-3 describes each briefly. These include psychophysiological insomnia, idiopathic insomnia, paradoxical insomnia, inadequate sleep hygiene, behavioral insomnia of childhood, insomnia comorbid with mental disorder, insomnia comorbid with medical condition, and insomnia due to drug or substance. ICSD-3 authors caution that “Despite the heuristic appeal of these various subtypes, it is often difficult to discriminate among them in clinical practice.” While this may be the case, paying attention to and understanding the overlapping complications of these subtypes can be essential for creating an effective treatment plan. The insomnia subtypes are described here to alert the clinician of possible insomnia nuances and complications.

Psychophysiological Insomnia. Psychophysiological insomnia involves conditioned arousal associated with the thought of sleeping. Objects related to sleep (e.g., the bed, the bedroom) likewise have become conditioned stimuli that evoke insomnia. Daytime adaptation is usually good (in contrast to impaired function in patients with psychiatrically related insomnia); however, there can be extreme tiredness, and the individual can become desperate. Psychophysiological insomnia often occurs in combination with stress and anxiety disorders, delayed sleep phase syndrome, and hypnotic drug use and withdrawal. Other features characteristic of psychophysiological insomnia include: (1)

excessive worry about not being able to sleep, (2) trying too hard to sleep, (3) rumination or inability to clear one's mind while trying to sleep, (4) increased muscle tension when getting into bed, (5) other somatic manifestations of anxiety, (6) ability to fall asleep when not trying to (e.g., when watching television), and (7) sleeping better away from own bedroom (including the sleep laboratory). In one sense, the individual has developed a performance anxiety concerning the ability to sleep, and autonomic nervous system conditioning reinforces the situation. Stimulus Control Therapy is well suited for treating psychophysiological insomnia (see behavioral treatments for insomnia). This nonpharmacologic approach is designed to improve the association between going to bed and being able to fall asleep. Because many patients with psychophysiological insomnia have developed poor sleep habits, improving sleep hygiene is usually beneficial. If muscle tension and rumination at bedtime are prominent features, relaxation therapy is a useful ancillary treatment.

Idiopathic Insomnia. Idiopathic Insomnia characterizes patients with a lifelong inability to obtain adequate sleep. The insomnia predates any psychiatric condition, and other etiologies must be ruled out or treated, including psychophysiological insomnia, environmental sleep disturbances, and practices constituting poor sleep hygiene. If the insomnia persists, then it is assumed that there is a defect in the neurologic mechanisms that govern the sleep–wake system. That is, the sleep homeostatic process is dysfunctional. Sleep restriction therapy may provide some benefits and will also give the clinician a clue to the limits of the patient's homeostatic process. Sleep restriction is a technique by which homeostatic drive is maximized by sleep schedule compression (see behavioral treatments). Unfortunately, patients with idiopathic insomnia will likely never have normal sleep. Treatment is difficult; however, improved sleep hygiene, relaxation therapy, and the use of hypnotic medicines are reportedly helpful. Although controversial, this group may require chronic pharmacotherapeutic intervention.

Paradoxical Insomnia. Paradoxical Insomnia, at its core, involves a dissociation between sleep and its usual attendant unconsciousness. In Paradoxical Insomnia, individuals think they are awake and have insomnia even though brain electrophysiologic activity pattern is consistent with the correlates of normal sleep. The discrepancy between subjective and objective sleep parameters is common in patients with various forms of insomnia; however, it is more extreme in paradoxical insomnia. That is, Paradoxical Insomnia is diagnosed when a patient complains of difficulty initiating or maintaining sleep, and no objective evidence of sleep disruption is found. For example, a patient sleeping in the laboratory reports taking more than an hour to fall asleep, awakening more than 30 times, and sleeping less than 2 hours the entire night. By contrast, the polysomnographic tracing showed sleep onset occurring within 15 minutes, few awakenings, a 90% sleep efficiency, and total sleep time greater than 7 hours. On many occasions, the patients report total lack of sleep with no or minimal daytime consequences. Paradoxical Insomnia can occur in individuals who are apparently free from psychopathology; however, it may represent a somatic delusion or hypochondriasis. Some patients with Paradoxical Insomnia have obsessional features with respect to somatic functions. Cognitive relabeling and/or diffusing the worry about being unable to sleep can help. Interestingly, anxiolytics can profoundly reduce the perception of sleeplessness without remarkably changing sleep physiologically.

In the past, paradoxical insomnia was called *pseudoinsomnia, sleep state misperception,* and *insomnia without objective findings*. These designations can be problematic because they imply invalidation of the complaint, thereby placing the clinician at odds with the patient. Making matters worse, this dissociation between the perception and physiology is very common in patients with schizophrenia. Interestingly, a study has shown an increased metabolic rate and maximum O_2 uptake in patients with *Paradoxical Insomnia* compared to normal controls. It is ironic that while most individuals readily acknowledge dreaming and understand that dreams constitute mental activity, they nonetheless are under the general mistaken impression that mental activity ceases during sleep. One might arrive at this conclusion based on the inability to recall anything between bedtime and morning arising. However, this confuses the amnesic property of sleep with lack of mentation. While it is true that, under normal circumstances, sleep and unconsciousness are coupled, in some cases these phenomena dissociate. Anxiety can provoke sleep-state misperception, and ruminative worry about not sleeping adds fuel to the fire. Thus if one lies in bed attempting to sleep and has ruminative thoughts, the individual may perceive themselves as awake, even though brain activity is consistent with the electrophysiologic correlates associated with normal sleep. A psychoeducational approach to informing the patient about this dissociation between brain activity and the perception of sleep can be helpful. Furthermore, the ruminations (which seem so urgent at the time but seem trivial in the morning, if remembered at all) may actually be a useful marker of sleep onset. If an individual can interpret the rumination as an indicator that they are asleep and it belays their worrying about not being able to sleep, the paradoxical insomnia often diminishes or even disappears.

Inadequate Sleep Hygiene. Inadequate Sleep Hygiene refers to insomnia produced by behaviors that are not conducive to good sleep. ICSD-1 defined inadequate sleep hygiene as “a sleep disorder due to the performance of daily living activities that are inconsistent with the maintenance of good quality sleep and full daytime alertness.” Many behaviors can interfere with sleep. Some of these behaviors increase arousal. For example, consuming caffeine or nicotine at night or engaging in excessive emotional or physical stimulation within a few hours of bedtime. Other behaviors interfere with sleep architecture, including daytime naps and a large variation of the daily sleep–wake schedule. It is widely believed that improving sleep hygiene can help relieve insomnia (see Table 23–2). It must be realized, however, that many activities related to sleep hygiene are lifestyle issues. Making a lifestyle change is difficult. Treatment should focus on only one or two problem areas at a time. Overwhelming the patient by attempting too many lifestyle changes or a complex regimen seldom succeeds.

Table 23–2.
Do's and Don'ts for Good Sleep Hygiene

	DO	DON'T
Maintain regular hours of bedtime and arising		
If you are hungry, have a light snack before bedtime		
Maintain a regular exercise schedule		
Give yourself an approximately an hour to wind down before going to bed		
If you are preoccupied or worried about something at bedtime, write it down and deal with it in the morning		
Keep the bedroom cool		
Keep the bedroom dark		
Keep the bedroom quiet		
Take naps		
Watch the clock so you know how bad your insomnia actually is		
Exercise right before going to bed in order wear yourself out		
Watch television in bed when you cannot sleep		
Eat a heavy meal before bedtime to help you sleep		
Drink coffee in the afternoon and evening		
If you cannot sleep, smoke a cigarette		
Use alcohol to help in going to sleep		
Read in bed when you cannot sleep		
Eat in bed		
Exercise in bed		
Talk on the phone in bed		

These recommendations are made when an individual experiences difficulty initiating sleep, maintaining sleep, or has early morning awakenings with difficulty resuming sleep. Additionally, most of these recommendations qualify as general good sleep health practices.

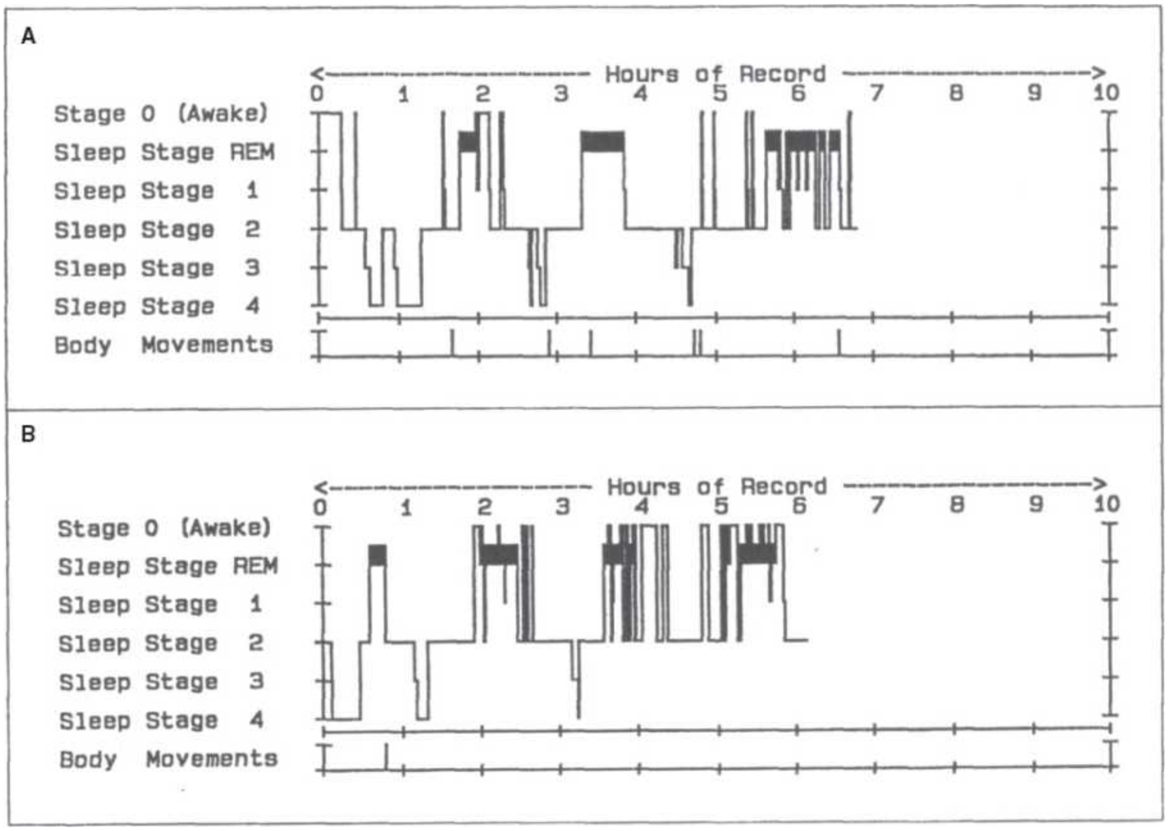

FIGURE 23–1. Sleep histograms showing normal sleep and insomnia. Sleep stage histograms comparing normal sleep (**Panel A**) with that found in a patient with major depressive disorders (**Panel B**). Difficulty maintaining sleep and early morning awakenings are common complaints in patients with depression. **Panel B** illustrates the electrophysiologic correlates of these complaints beginning, in this case, after approximately 2 hours of sleep. Sleep continuity becomes disrupted as morning approaches. Also present is a markedly reduced latency to REM sleep. This sleep feature is characteristic of this patient population and is thought by some to reflect cholinergic–aminergic imbalance.

Behavioral Insomnia of Childhood. Behavioral Insomnia of Childhood results from the child’s dependency on specific stimulation, objects, or setting for initiating sleep or returning to sleep. Without the presence of the teddy bear or parent, sleep onset is significantly delayed. Alternatively, without adequate limit setting by the caregiver, bedtime stalling (“Dad, I’m thirsty – can I get some water?”), or bedtime refusal (“I’m not tired! I don’t want to go to sleep!”) can ensue. *Limit-setting Sleep Disorder* occurs when a child takes advantage of an inadequately enforced bedtime schedule. Childhood insomnia, as it is sometimes called, involves a child refusing to or delaying going to bed when the caretaker stipulates. If unresolved, when the child reaches adolescence and can set their own schedule, inadequate sleep hygiene, insufficient sleep syndrome, or irregular sleep–wake pattern may become the problem. Delay strategies employed by the child include getting up to use the bathroom, requests for another drink, wanting another bedtime story, or complaints of hunger. Sometimes children will claim that they are afraid of the dark, monsters under the bed, or some other fictitious creation. The well-intentioned parent may be manipulated out of emotional concern. The problem often begins when the child can climb out of the crib or has been moved to a bed. The caregivers' knowledge and ability to properly set limits is critical; therefore, the education of caregivers can provide effective treatment.

Insomnia Comorbid With Mental Disorder. Insomnia Comorbid with Mental Disorder is the most common form of disorders of initiating and maintaining sleep. Thirty-five percent of patients seen in sleep disorders centers with insomnia as their chief complaint had a mental disorder, and half of these patients had a mood disorder.

Ninety percent of patients with **Major Depressive Disorder (MDD)** have insomnia. Insomnia is a risk factor (or marker) for depression on 3-year follow-up, conferring an odds ratio of 3.95 compared to an individual without insomnia. Insomnia is also an independent risk factor for suicide in patients with MDD, and 1 month after a trauma, insomnia is predictive of who will develop PTSD 1 year after trauma. It has been suggested that treating insomnia may help prevent mental disorders, especially depression. Sleep disturbances using EEG criteria in MDD include: (1) generalized sleep disturbance (increased sleep latency, increased nocturnal awakenings, and early morning awakenings), (2) slow wave sleep decreased in the first NREM-REM cycle with delta activity shifts to the second NREM period, (3) latency to REM sleep shortened, (4) REM sleep occurring earlier in the night, and (5) REM density increased (especially early in the night) (see Fig. 23–1). Selective REM sleep deprivation alleviates depression. Furthermore, this antidepressant action can persist for several days or more. Interestingly, most antidepressant medication suppresses REM sleep (including selective serotonin reuptake inhibitors, tricyclic antidepressants, and monoamine oxidase inhibitors). Arecoline (a cholinergic agonist) infusion will induce REM sleep in depressed patients, and scopolamine withdrawal mimics depression in normal subjects (including EEG sleep changes). These data support the

Cholinergic-Aminergic Imbalance theory of Major Depression. While it still holds that any drug capable of suppressing REM sleep has potential antidepressant properties, a couple of antidepressants do not suppress REM sleep (e.g., bupropion and nefazodone). Thus, the theory needs reformulation. Restated, REM suppression is sufficient but not necessary for antidepressant action. Treating insomnia while treating MDD may improve antidepressant effect. In a study on patients meeting DSM-IV criteria for both MDD and insomnia (*n* = 545), each received a morning dose of fluoxetine and were randomized to nightly eszopiclone 3 mg (ESZ+FLX) or placebo (PBO+FLX) for 8 weeks. Subjective sleep and daytime function were assessed weekly. Patients in the ESZ+FLX group had significantly decreased sleep latency, wake time after sleep onset, increased total sleep time, sleep quality, and depth of sleep. Eszopiclone co-therapy also produced significant and progressive improvement in mood when compared to fluoxetine alone. And the improvements of adjunctive insomnia therapy persisted for 2 weeks after the eszopiclone treatment was discontinued; fluoxetine was continued.

Bipolar disorder profoundly adversely affects sleep. Patients with mania and hypomania seldom complain of sleep problems even though they sleep only for a short duration (2 to 4 hours per night), have very prolonged latency to sleep, and sometimes have reduced slow wave sleep. When they enter the depressed phase, they are more likely to be seen at a sleep disorders center. Clinically, it is also noted that patients with bipolar disorder, if they break from their sleep–wake routine and stay up very late or all night, may provoke a manic episode.

Patients with **Schizophrenia** have no consistent EEG sleep changes except that they do not have REM sleep rebound in response to REM sleep deprivation. The only other consistent finding is that patients with schizophrenia frequently deny having slept even though EEG-EOG-EMG sleep appears normal. Patients with anxiety and personality disorders often have sleep-onset and sleep maintenance insomnia. Short REM sleep latencies and reduced slow wave sleep are reported in some studies; however, the finding is not specific to schizophrenia and is not consistent.

Patients with **Generalized Anxiety Disorder** worry excessively about multiple events, for more days than not, for at least 6 months; have difficulty controlling the worry; and the worrying causes at least three of the following: disturbed sleep, muscle tension, irritability, difficulty concentrating, restlessness, being easily fatigued. Although insomnia is one of the key symptoms, data addressing nonsedating anxiolytic efficacy for treating disturbed sleep are sparse. In a couple of randomized, placebo-controlled studies, the benzodiazepine receptor agonist (BZRA) zopiclone improved sleep onset and daytime anxiety when compared to benzodiazepines (BZDs). However, zopiclone is not available in the United States.

Insomnia Comorbid With Medical Condition. Insomnia accompanies many medical and neurologic conditions. Given pain's potential for disturbing sleep, all medical conditions producing pain can (and usually do) disturb sleep. Unfortunately, a synergy exists between pain and sleep such that poor sleep lowers the pain threshold. This vicious cycle can present a difficult treatment challenge. However, reducing pain can also improve sleep, and improving sleep can reduce pain. Thus, a two-pronged approach to pain and sleep can prove beneficial. In other medical conditions, the sleep disturbance appears to be secondary. For example, sleep-related gastroesophageal reflux disease (GERD) is often associated with insomnia. Treating the reflux results in sleep improvement but insomnia treatments seldom, if ever, relieve nocturnal GERD. Patients with chronic obstructive lung disease commonly suffer from both sleep-onset and sleep maintenance insomnia. Treating insomnia does not appear to ameliorate COPD. Neurodegenerative diseases are frequent associates of sleep disorders, including insomnia, hypersomnolence, parasomnias, and circadian rhythm disorders. Discussing specific medical and neurologic disorder associations with sleep disorders is beyond this chapter's scope, and the reader is referred to Chokroverty (2017) for details.

Insomnia Due to Drug or Substance. Many prescription drugs, even when taken properly, can disturb sleep. This includes antidepressants (i.e., fluoxetine), antihypertensives, corticosteroids, hypolipidemic medications, antiparkinsonian drugs, decongestants (i.e., pseudoephedrine), anorectics, stimulants, and antiepileptic medications. In addition, some sedating medications cause rebound insomnia when discontinued.

Alcohol and hypnotic use initially promote sleep onset because of their sedating properties. A problem occurs when sleep quality is adversely affected, tolerance develops after chronic use, or withdrawal begins.

Alcohol may relax a tense person and thereby decrease latency to sleep; however, sleep later in the night will usually be fragmented by arousals. As tolerance develops to the alcohol, greater amounts or more frequent dosing are needed to sustain the effects. Furthermore, during withdrawal or after tolerance develops, insomnia may rebound to a level more severe than the initial disturbance. If sleep is considered a behavior, and this behavior becomes dependent on the use of alcohol, then this is a form of alcoholism. Interestingly, for many patients with alcohol dependence, insomnia predates alcohol use and persists even during prolonged periods of abstinence.

Caffeine (the active ingredient in coffee) and theobromine (the active ingredient in chocolate) are methylxanthines, and they act as psychostimulants in the mammalian central nervous system (CNS). Psychostimulants increase sleep latency, reduce sleep efficiency, and decrease total sleep time. Caffeine’s half-life is 3 to 7 hours and may interfere with sleep when consumed in large quantities throughout the day or even in smaller portions closer to bedtime. Some individuals are hypersensitive to methylxanthine, and any coffee or chocolate can trigger difficulty falling asleep or awakening after a couple of hours of sleep with difficulty getting back to sleep. Finally, abuse of illicit substances, particularly stimulants (such as cocaine and amphetamines), interferes with sleep onset and sleep maintenance. Unlike with alcohol, discontinuation of these substances will cause hypersomnolence.

Short Sleeper. People who fall under this category require less than 5 hours of sleep per 24-hour period to maintain normal daytime functioning and mood. The patient may be distressed about not sleeping. However, if the short sleep duration does not provoke adverse daytime consequences, functional impairment, or is associated with relevant comorbid conditions, full Insomnia Disorder criteria are not met. Being a short sleeper appears to run in families, and mutations in two specific genes (DEC2 and ADRB1) and a variant of the BHLHE41 gene are seen in short sleeper families.

Diagnostic Workup of Insomnia

Diagnostic workup of insomnia may include thyroid function tests, glycosylated hemoglobin level, complete blood count, serum iron studies, ferritin level, liver function tests, renal functions tests, and other tests that may be indicated depending on the clinical presentations and comorbid conditions.

Sleep diaries are a cost-effective and reliable way to assess the sleep–wake cycle in individuals with insomnia. The most widely used self-evaluating questionnaires are the Insomnia Severity Index (ISI) and Epworth Sleepiness Scale. Polysomnography is not routinely recommended for the initial assessment of individuals with insomnia but is used in the assessment of patients suspected of suffering from other sleep disorders (such as sleep apnea, periodic limb movement disorder) associated with insomnia, and individuals with chronic insomnia disorders that fail to respond to treatment.

Treating Insomnia

In general, nonpharmacologic interventions are the first line for insomnia treatment. However, the use of pharmacologic agents is frequently requested by patients due to their faster effect, and therefore the clinician should be aware of the risk of dependency and try to shorten the duration of drug use, and ensure the focus of treatment is not removed from nonpharmacologic therapy. If nonpharmacologic therapy is successful, then the patient should start to gradually discontinue drug treatment at the first opportunity.

Nonpharmacologic Treatment With Cognitive Behavioral Therapy for Insomnia (CBTi). This treatment modality combines behavioral and cognitive techniques to overcome dysfunctional sleep behaviors and misperceptions, and distorted, disruptive thoughts about sleep. The therapist begins with a careful clinical interview to assess the insomnia’s etiology, chronicity, severity, associations, and comorbid conditions. A treatment plan is then designed using relevant and appropriate cognitive and behavioral techniques. These may include universal sleep hygiene, stimulus control therapy, sleep restriction therapy, relaxation therapies and biofeedback, cognitive therapy, and occasionally, paradoxical intention. With recent advances in technology and telehealth, various forms of CBTi can be delivered with no need for in-person visits.

Studies repeatedly show significant, sustained improvement in sleep symptoms with CBTi. Improvements include reduced wakefulness duration, decreased number of awakenings, and shorter latency to sleep onset. Short-term benefits are similar to that of medication, but CBTi tends to have lasting benefits, even 36 months after treatment. With the cessation of the medication, insomnia frequently returns and is sometimes accompanied by rebound insomnia. CBTi has not been shown to produce any adverse effects. There are no established “best practice” guidelines for the length or quantity of sessions. CBTi, however, is not without limitations. Most data do not compare the efficacy of the individual components (described below) of CBTi. However, sleep hygiene education alone does not appear to improve sleep. Intuitively, the multicomponent approach addresses many of the variables contributing to insomnia. Other limitations of CBTi include lack or unavailability of trained specialists, cost of sessions, and noncoverage by insurance carriers.

The effects of CBTi take longer to emerge than the effects of medications. Individuals are often desperate when they finally seek treatment for their insomnia. This makes it difficult to convince them to try a therapy that may require several weeks before it provides relief. Also, patients must be active participants in this type of therapy. Many individuals not only want a “quick fix,” but they also want to undergo a procedure or have something administered rather than be involved in the therapeutic process. For optimal CBTi, patients must commit to multiple sessions and be open to the idea that modifying thoughts and behaviors about sleep can improve insomnia symptoms. The “quick fix” model is common in primary care; by contrast, psychiatrists are accustomed to a delayed response from their experience with antidepressants and other psychotropic medicines. Consequently, psychiatrists may be more comfortable recommending CBTi than other practitioners.

Although firmly focused on cognitive and behavioral issues, it helps to extend CBTi just slightly into the psychodynamic sphere. For some patients with longstanding difficulty sleeping, being an insomniac becomes an important part of their identity. There may be primary or secondary gain to such identification. It is the negative emotional response (i.e., anger at the inability to control one’s sleep, feeling like a failure because one can’t sleep) to insomnia that contributes to its chronicity. In general, these individuals tend to internalize rather than express emotion, feel a heightened need for control, experience interpersonal difficulties, and have significant discontent with past events. For this subset of people, if the emotional response is not addressed, there is more likely to be a limited response to CBTi or a relapse of insomnia over time. The clinician who is attuned (i.e., to the patient’s tendency to view something as a failure rather than a challenge) will be better able to intercept barriers to treatment. “As chronic insomnia is an extremely psychologically painful condition, a high level of motivation and willingness to explore oneself, at least with a specific focus, is often present.”

UNIVERSAL SLEEP HYGIENE. The focus of universal sleep hygiene is on modifiable environmental and lifestyle components that may interfere with sleep as well as behaviors that may improve sleep. Especially because some of these behaviors are difficult to change, only one or two items that the patient and clinician collaboratively choose should be addressed at a time. This will give the patient the best chance at a successful intervention. Sleep enhancing directives are enumerated in Table 23–2. Often a few simple alterations in a patient’s habits or sleep environment can be effective. The clinician, however, needs to spend time reviewing both the patient’s routine and its irregularity. In some respects, the essence of insomnia is its variability. The day-to-day changes in behavior and the changing severity of sleeplessness can obscure the factors responsible for the problem. A carefully explained sleep hygiene program, with follow-up, represents a fairly inexpensive but effective intervention. Furthermore, improving sleep habits can enhance sleep even when the major cause of insomnia is physical.

STIMULUS CONTROL THERAPY. Stimulus control therapy is a deconditioning paradigm developed by Richard Bootzin and colleagues at the University of Arizona. This treatment aims to break the cycle of problems commonly associated with difficulty initiating sleep. By attempting to undo conditioning that undermines sleep, stimulus control therapy helps reduce both primary and reactive factors involved in insomnia. The rules attempt to enhance stimulus cues for sleeping and diminish associations with sleeplessness. The instructions are simple; however, they must be followed consistently. The first rule is to go to bed only when sleepy in order to maximize success. Second, use the bed only for sleeping. Do not watch television in bed, do not read, do not eat, and do not talk on the telephone while in bed. Third, do not lie in bed and become frustrated if unable to sleep. After a few minutes (do not watch the clock), get up, go to another room, and do something nonarousing until sleepiness returns. The goal is to associate the bed with rapid sleep onset. Rule three should be repeated as often as needed. The fourth and final instruction attempts to enhance the mechanisms underlying the circadian and sleep-wake cycles; that is, awaken at the same time every morning (regardless of bedtime, total sleep time, or day of the week) and totally avoid napping. Stimulus control therapy does work; however, you may not see results during the first few weeks or month. If continually practiced, the bouts of insomnia lessen in both frequency and severity.

SLEEP RESTRICTION THERAPY. Sleep restriction therapy is designed to increase sleep efficiency by decreasing the amount of time spent awake while lying in bed. Developed by Arthur Spielman, this therapy specifically targets those patients who lay awake in bed, unable to sleep. Restricting time in bed can help consolidate sleep. If the patient reports sleeping only 5 hours of a scheduled 8-hour time in bed, reduce the time in bed. However, it is advised not to reduce bedtime to less than 4 hours per night and to warn the patient about the hazards of daytime sleepiness. Sleep at other times during the day must be avoided, except for the older adults, who may take a 30-minute nap. The clinician then monitors sleep efficiency (time asleep as a percentage of the time in bed). When sleep efficiency reaches 85% (averaged over five nights), time in bed is increased by 15 minutes. Sleep restriction therapy produces a gradual and steady decline in nocturnal wakefulness.

RELAXATION THERAPY AND BIOFEEDBACK. The most important aspects of relaxation therapy are that it be performed properly and over-learned. Self-hypnosis, progressive relaxation, guided imagery, and deep breathing exercises are all effective if they produce relaxation. The goal is to find the optimal technique for each patient, but not all patients need help relaxing. **Progressive muscle relaxation** is especially useful for patients who experience muscle tension. Purposefully tense (5 to 6 seconds) and then relax (20 to 30 seconds) muscle groups beginning at the head and ending at the feet. Appreciate the difference between tension and relaxation. **Guided imagery** has the patient visualize a pleasant, restful scene, engaging all of their senses. **Breathing exercises** are practiced for at least 20 minutes per day for 2 weeks. Once mastered, use the technique once at bedtime for 30 minutes. If it does not work, try again another night. It is important that the technique not become associated with failure to fall asleep. **Abdominal breathing** is described below. The patient must become comfortable with each step before moving on to the next. First, in the supine position, breathe normally through your mouth or nose, whichever is more comfortable, and attend to your breathing pattern. Second, while maintaining that rhythm, begin to breathe more with your abdomen and less with your chest. Third, pause for a half-second after each breath cycle (in and out) and evaluate the breath. How did it feel? Was it smooth? Eventually, each breath will become uniform and smooth. Fourth, find a place where you can best feel the air move in and out. Concentrate on that spot and on the air moving in and out. Fifth, visualize intrusive thoughts as floating away; stop practicing and try again later if there are too many thoughts. **Biofeedback** provides stimulus cues for physiologic markers of relaxation and can increase self-awareness. The machine can measure muscle tension in your forehead or finger temperature. Finger temperature will rise when you become more relaxed. Patients require careful and adequate training; simply giving them an instruction tape is not especially helpful. Techniques are ideally mastered during the day for several weeks before application to the sleep problem; this is best achieved outside of the bed. By the time the techniques are applied in bed, the skill should be automatic. Relaxation techniques readily lend themselves to being combined with sleep hygiene and stimulus control therapies. Sometimes, they make for good distractions from a person thinking about their inability to sleep. The ruminations fuel insomnia and if the ruminator can be distracted, they may sleep better.

COGNITIVE THERAPY. This effective, validated treatment for a variety of psychiatric conditions, including major depression and generalized anxiety, has been adapted for use with insomnia. The cognitive aspect of insomnia treatment targets the negative emotional response to an appraisal of a sleep-related situation. The negative emotional response is thought to produce emotional arousal, which in turn contributes to or perpetuates insomnia. People who have maladaptive cognitions tend to exaggerate the negative consequences of insomnia: “there must be something really wrong with me if I can’t fall asleep in 40 minutes.” They also tend to have unrealistic expectations about their sleep requirements: “if I don’t sleep eight hours a night, then my whole day will be ruined.” The first step is to identify these cognitions, next challenge their validity, and finally substitute them with more adaptive cognitions (see Table 23–3). This is most easily illustrated by example, as in the box below.

Table 23–3.
Catastrophizing and Alternative Thoughts Scenario

Situation	Alarm clock goes off at 6:02 am Monday
Thought	“I hardly slept at all last night. I should be able to get more sleep. There must be something wrong with me. Great, I’ll be too tired to concentrate on anything today.”
Behavior/Feeling	Hit snooze to try to get 9 more minutes of sleep. Despair 70% Irritated 75%
Evidence	“Too tired to concentrate” For: I usually feel tired on Mondays. I lost my keys last week. Against: I just got a promotion, so I must be doing something right
Alternative balanced thought	“I did get some sleep last night and I usually can concentrate on my work.”
Feeling	Despair 50% Irritated 60%

A 42-year-old male presents to the office with a 5-year history of insomnia. He identifies being fired from his job and the birth of a colicky baby as precipitating factors in his inability to sleep. However, even after finding a new position with better hours and pay, and with the child now sleeping through the night, he continues to experience difficulty falling and staying asleep. Perpetuating factors include low back pain and a spouse with periodic limb movement disorder. He reports spending 8 to 9 hours in bed each night and sleeping only 4 to 5 hours intermittently. He watches 1 hour of TV in bed before turning out the light for bedtime. He spends hours watching his minutes tick away. He does not wake feeling rested and, when his alarm goes off, he is frequently already awake and has the thoughts, "I hardly slept at all last night. I should be able to get more sleep. There must be something wrong with me. Great, I'll be too tired to concentrate on anything today."

Examples of his maladaptive thoughts: ***"I should be able to get more sleep."*** This faulty appraisal of sleeping ability may relate to a need for control over sleep. This need for control interferes with having a more laissez-faire attitude about a few missed hours of rest. Such thoughts also lead to feelings of frustration and anger. ***"Great, I'll be too tired to concentrate on anything today."*** This is a misattribution of daytime impairment due to poor sleep. The patient is also magnifying the negative/ discounting the positive and engaging in black-and-white or all-or-nothing thinking. Could he be too tired to concentrate on some things but not all things? Might his inability to concentrate be due to a myriad of other factors? ***"There must be something wrong with me [if I can't get enough sleep]."*** Catastrophizing and emotional reasoning are at play here: just because you have a feeling, doesn't mean that the thought/feeling is true. A strongly held belief that sleeplessness negatively impacts physical and mental health can set off catastrophizing.

ACCEPTANCE AND COMMITMENT THERAPY (ACT). Acceptance and Commitment Therapy (ACT) includes six processes or skills and is another modality for the management of insomnia. These processes include Acceptance, Cognitive Defusion, Being Present, Self as Context, Values, and Committed Action. In fact, after receiving these skills, the patient increases psychological flexibility. Psychological flexibility is the ability to behave adaptively and in accordance with values despite having painful experiences. ACT has promising effects on insomnia, anxiety, and depression management.

PARADOXICAL INTENTION. This is a cognitive technique with conflicting evidence regarding its efficacy. In clinical practice, compliance is often a barrier, but it does work for a limited number of patients. The theory is that performance anxiety interferes with sleep onset. So when the patient tries to stay awake for as long as possible, rather than fall asleep, performance anxiety will be reduced, and sleep latency will improve.

Pharmacologic Treatment. For many years, BZDs were the most commonly prescribed sedative hypnotic medications for treating insomnia. BZRAs have replaced BZDs as the standard for sedative hypnotic medications used to treat insomnia. BZRAs include zolpidem, zaleplon, and eszopiclone. Subsequent development of a low-dose antihistamine (doxepin), melatonin receptor agonists (ramelteon and tasimelteon), and orexin antagonists (suvorexant and lemborexant) have more recently augmented the armamentarium of medications approved for treating insomnia. However, unapproved off-label (and not recommended) use of sedating antidepressants is common. Low-dose atypical antipsychotics (olanzapine, risperidone, and quetiapine) are effective in the treatment of paradoxical insomnia in patients who manifest with delusional features and do not respond to psychoeducation. These agents may also be helpful in patients with other subtypes of insomnia who have not responded to other sedative hypnotic agents. It seems they can be used to treat insomnia; however, the risk of adverse side effects such as metabolic syndrome should not be overlooked. Additionally, various over-the-counter (OTC) sleep aids are available. Nonprescription formulas include sedating antihistamines, protein precursors, and other substances. L-tryptophan was popular and readily available at health food stores until an outbreak of eosinophilia led to it being pulled off the shelves. Melatonin is the leader among self-administered food additives believed by some to alleviate sleeplessness. Essentially, low-dose melatonin can improve sleep when used to align or re-entrain the circadian rhythm with the desired sleep–wake schedule.

Prescription medicines are rigorously tested in clinical trials; therefore, they hold an advantage over the virtually untested OTCs. To attain FDA approval as a hypnotic, a medication must be safe and effective. Most hypnotic medications are approved for short, not long-term, use. Exceptions include zolpidem-modified release, eszopiclone, and ramelteon, all of which are approved for long-term therapy. When properly used, hypnotics can provide immediate and adequate relief from sleeplessness. Insomnia, however, usually returns upon discontinuation of dosing.

HYPERSOMNOLENCE DISORDER

The term hypersomnolence broadly refers to excessive sleepiness, an excessive quantity of sleep, and drowsiness with reduced vigilance during usual periods of wakefulness. Excessive sleepiness can be a serious, debilitating, potentially life-threatening condition. It affects not only the afflicted individual but also their family, coworkers, and the public at large. Although excessive sleepiness can arise from insufficient sleep, disrupted sleep, or desynchrony with one's circadian rhythm, Hypersomnolence Disorder is thought to stem from some basic neurologic sleep regulation dysfunction.

Hypersomnolence adversely affects attention, concentration, memory, and higher-order cognitive processes. Serious results of sleepiness include failure at school, loss of employment, motor vehicle accidents, and industrial disasters. The transportation industry is particularly prone to sleep-related accidents, including trucking, railroad, marine, and aviation. There are many sleep disorders associated with excessive daytime sleepiness; however, Obstructive Sleep Apnea Hypopnea (OSAH) is by far the most common dyssomnia seen in sleep disorder centers. By contrast, Hypersomnolence Disorder is a relatively rare condition.

Diagnostic Criteria

Hypersomnolence Disorder should be evaluated according to six criteria. DSM-5-TR sets these forth as follows: (1) how it influences wakefulness notwithstanding adequate sleep time (7 hours or more for the adult); (2) its frequency; (3) its adverse effect on functioning or emotional stability; (4) that the sleepiness is not better explained by whether it occurs in conjunction with some other sleep disorder, (5) medication or substance use, or (6) some other psychiatric, neurologic, or medical condition. Other conditions may be present (and should be specified); however, they must not better explain the hypersomnolence. All criteria must be met.

The primary criteria descriptively relate to how hypersomnolence affects wakefulness. Specifically, one or more of the following must be present: (a) recurrent sleep episodes or lapses into sleep within the same day; (b) a prolonged (9 hours or more) sleep episode that is not refreshing; (c) difficulty achieving full wakefulness upon abrupt awaking (sometimes called, *sleep inertia*). The frequency criterion stipulates that hypersomnolence must occur three times (or more) weekly for at least 3 months. The influence on wakefulness must be associated with "significant distress or impairment in cognitive, social, occupational, or other important areas of functioning." To diagnose Hypersomnolence Disorder, the symptoms must not be attributable to the use of a medication or substance.

When the diagnosis of Hypersomnolence Disorder is made, the clinician should specify if there are comorbid conditions (be they sleep disorder, psychiatric, neurologic, or medical) and whether the hypersomnolence duration is acute (less than 1 month), subacute (1 to 3 months' duration), or persistent (more than 3 months). The diagnosis should also include a specification for severity based on the patient's difficulty maintaining alertness while socializing, inactively sitting, reading, watching television, working, driving, or engaging in other activities. The difficulty can result from extreme drowsiness, nearly irresistible sleepiness, or actual lapses into sleep. The clinician should specify "mild" if difficulties occur 1 to 2 days per week, "moderate" if 3 to 4 days per week, and "severe" if 5 to 7 days per week.

Characteristics and Hypersomnolence Subtypes

Hypersomnolence Disorder presents in several forms. It may be associated with very long sleep periods after which the individual remains sleepy (see Fig. 23–2). The disorder can also occur with adequate but not long sleep periods. Sleep in patients with Hypersomnolence Disorder is usually well preserved, and sleep efficiency remains high even in forms associated with extended sleep schedules (12 hours or more). Furthermore, the patient readily falls asleep if given an opportunity to nap the following day. Sleep sometimes has elevated slow wave sleep; however, the EEG sleep pattern is essentially the same as that found in normal individuals who are sleep deprived. Unlike a sleep-deprived individual, the sleep pattern continues in this profile even after several nights of extended sleep. The etiology of Hypersomnolence Disorder is not known; however, a CNS cause is presumed. Some individuals with Hypersomnolence Disorder are HLA Cw2 positive, have autonomic nervous system dysfunctions, and have other affected family members. Some cases (approximately 10%) begin with a viral infection and quickly evolve into more permanent hypersomnolence (e.g., infectious mononucleosis, viral pneumonia, Guillain-Barre Syndrome). There also appears to be a familial form of Hypersomnolence Disorder with autosomal-dominance inheritance.

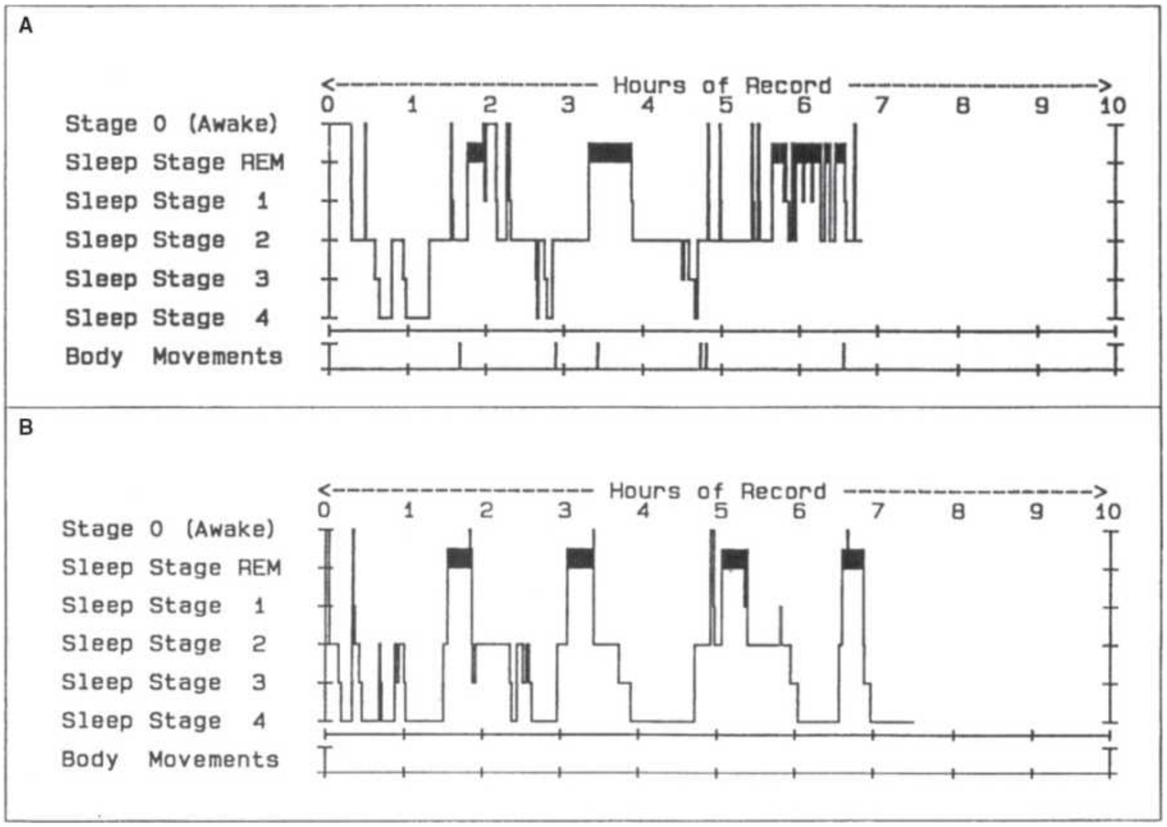

FIGURE 23–2. Sleep stage histograms comparing a normal sleep profile with that of a patient with hypersomnolence. **Panel A** illustrates the sleep pattern recorded in a healthy young adult. His sleep was interrupted several times by awakenings associated with other concurrent laboratory procedures; however, all parameters were within normal limits. **Panel B** depicts the sleep pattern of a patient with severe daytime sleepiness. The patient did not have narcolepsy or apnea. In the laboratory, sleep onset was rapid, sleep continued virtually without interruption, and he was extremely difficult to arouse. This recording was terminated after 7.5 hours to begin daytime testing; however, the patient's sleep revealed little indication of progressing toward a lighter state. In contrast to the normal sleep pattern, slow-wave sleep duration was elevated and it continued to emerge in alternation with REM sleep throughout the night. The patient awoke feeling unrefreshed and not satisfied with his sleep.

DSM-5-TR does not include descriptions of Hypersomnolence Disorder subtypes; however, ICSD-2 and ICSD-3 discuss some of these variants. Perhaps the intriguing of these is Kleine–Levin syndrome. Kleine–Levin predominantly afflicts males in early adolescence; however, it can occur later in life and in females. In its classic form, the recurrent episodes are associated with extreme sleepiness (18- to 20-hour sleep periods), voracious eating, hypersexuality, and disinhibition (e.g., aggression). Episodes typically last for a few days up to several weeks and appear once to 10 times per year. A monosymptomatic hypersomnolence form can occur. The frequency of the HLA DQB1*02 is increased in patients with this syndrome.

Medical conditions known to cause hypersomnolence include head trauma, stroke, encephalitis, Parkinson disease, inflammatory conditions, tumors, genetic diseases, and neurodegenerative diseases. Recurrent hypersomnolence can also occur related to the menstrual cycle and appears in months of menarche. The symptoms typically last for 1 week and resolve with menstruation. Treatment with oral contraceptives is effective, and therefore the disorder is thought to be secondary to a hormone imbalance.

Of course, sleepiness can be provoked by many prescription medications and recreational substances. Use or abuse of sedative hypnotics, sedating antihistamines, sedating antidepressants, antiepileptics, neuroleptics, and opioid analgesics can cause sleepiness. Hypersomnia may also be provoked by withdrawal from cocaine, amphetamines, caffeine, and nicotine.

Treating Hypersomnolence Disorder

Hypersomnolence Disorder is usually managed pharmacologically. Although there are no medications indicated for its treatment, stimulants are commonly used with varying degrees of success. The wake-promoting substances (modafinil, armodafinil, solriamfetol, and pitolisant) or traditional psychostimulants (amphetamines and their derivatives and methylphenidate) sometimes help manage the sleepiness. In addition to drug therapies, the overall therapeutic approach usually includes lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance (if stimulants are used), and careful monitoring of refills, general health, and cardiac status.

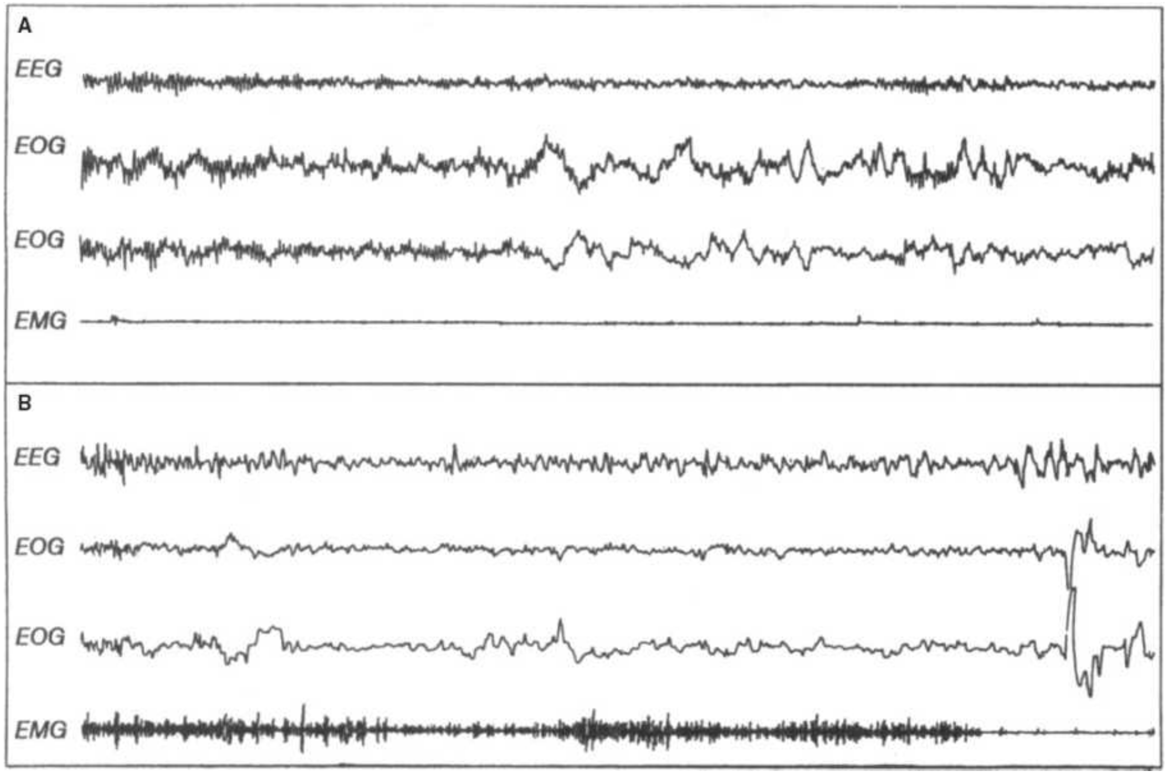

FIGURE 23–3. Polysomnographic tracing comparing normal sleep onset with that of a patient with narcolepsy. Each panel illustrates approximately 30 seconds of polysomnographic recording beginning with relaxed wakefulness. **Panel A** (normal sleep progression) shows a reduction of EEG alpha activity and development of slow rolling eye movements. **Panel B** shows the normally expected abatement of EEG alpha activity associated with increased theta activity and the appearance of a few slow eye movements. However, within 25 seconds (far right of figure) a swift loss of muscle tone occurs accompanied by rapid eye movements. This appearance of sleep-onset REM sleep (SOREM) characterizes narcolepsy and is part of the diagnostic criteria.

NARCOLEPSY

For decades, Narcolepsy was characterized by a tetrad of symptoms. These included (1) excessive sleepiness, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations. Hypersomnolence and cataplexy always served as the key symptoms. Cataplexy involves the sudden loss of muscle tone, usually with continuing full or partial consciousness. Cataplexy is commonly precipitated by laughter. However, other strong emotions can "trigger" cataplexy. Cataplexy severity ranges widely from transient weakness in the knees to total paralysis while the patient is fully conscious. Episodes may last from several seconds to minutes. Usually, the patient cannot speak and may fall to the floor. According to DSM-5-TR, in children (or during the first 6 months of onset), cataplexy can be recognized by “spontaneous grimaces or jaw-opening episodes with tongue thrusting or a global hypotonia, without any obvious emotional triggers.”

Sleep paralysis and hypnagogic (or hypnopompic) hallucinations are nonspecific symptoms and may occur in isolation or in conjunction with other sleep disorders. Polysomnographic sleep studies typically revealed abnormal sleep architecture in which REM sleep occurs soon after sleep onset both at night and during daytime naps (see Fig. 23–3). This, in connection with the symptom tetrad, suggested narcolepsy-involved REM sleep intrusion, presumably resultant from dysfunction of REM sleep generator gating mechanisms. The tetrad features resembled REM sleep characteristics. Sleep paralysis is similar to the muscle atonia occurring during REM sleep and hypnagogic hallucinations resembling dreaming. Nocturnal sleep is often fragmented, and there can be considerable sleep disturbance. Patients may experience depression associated with narcolepsy, especially when not treated. Social isolation, difficulty with academics and employment, and fear of driving contribute to a sense of loss experienced by patients with narcolepsy.

The discovery that Narcolepsy is strongly associated with a hypocretin (orexin) deficit radically changed diagnostic practice. Recent works suggest that selective loss of hypocretin-producing neurons in narcolepsy with cataplexy may have an autoimmune nature. Narcolepsy diagnostic criteria now include variants without cataplexy. ICSD-3 has separate criteria for Narcolepsy with and without cataplexy. DSM-5-TR handles these variants with specific stipulations.

Diagnostic Criteria

The diagnostic criteria for narcolepsy presented in this section are based on the criteria set forth in DSM-5-TR (Table 23–4).

DSM-5-TR also indicates that the clinician should specify whether the diagnosis is: (a) Narcolepsy without cataplexy but with hypocretin deficiency, (b) Narcolepsy with cataplexy but without hypocretin deficiency, autosomal dominant cerebellar ataxia, deafness, and narcolepsy (because these conditions can be associated with low or intermediate CSF hypocretin levels), (c) Autosomal dominant narcolepsy, obesity, and type 2 diabetes (because patients with obesity and type 2 diabetes can have low CSF hypocretin levels), or (d) Narcolepsy secondary to another medical disorder (because some diseases or head trauma can be associated with hypocretin neuron destruction).

Table 23–4.
DSM-5-TR Diagnostic Criteria for Narcolepsy

A. Recurrent periods of an irrepressible need to sleep, lapsing into sleep, or napping occurring within the same day. These must have been occurring at least three times per week over the past 3 months.

B. The presence of at least one of the following:
   1. Episodes of cataplexy, defined as either (a) or (b), occurring at least a few times per month:
      a. In individuals with long-standing disease, brief (seconds to minutes) episodes of sudden bilateral loss of muscle tone with maintained consciousness that are precipitated by laughter or joking.
      b. In children or in individuals within 6 months of onset, spontaneous grimaces or jaw-opening episodes with tongue thrusting or a global hypotonia, without any obvious emotional triggers.
   2. Hypocretin deficiency, as measured using cerebrospinal fluid (CSF) hypocretin-1 immunoreactivity values (less than or equal to one-third of values obtained in healthy subjects tested using the same assay, or less than or equal to 110 pg/mL). Low CSF levels of hypocretin-1 must not be observed in the context of acute brain injury, inflammation, or infection.
   3. Nocturnal sleep polysomnography showing rapid eye movement (REM) sleep latency less than or equal to 15 minutes, or a multiple sleep latency test showing a mean sleep latency less than or equal to 8 minutes and two or more sleep-onset REM periods.

The variant of narcolepsy, previously called *Narcolepsy Due to a Medical Condition,* often exhibits cataplexy. The cataplexy can be provoked by tumors or sarcoidosis of the hypothalamus; multiple sclerosis plaques affecting the hypothalamus; paraneoplastic syndrome with anti-Ma2 antibodies; Neimann–Pick type C disease (especially in children younger than 5); and possibly Coffin–Lowry syndrome. Cataplexy is usually absent in narcolepsy associated with multiple sclerosis, myotonic dystrophy, Prader–Willi syndrome, Parkinson disease, and multiple system atrophy. Narcolepsy due to a medical condition included what used to be called Posttraumatic Hypersomnia, which may or may not present with cataplexy.

Treating Narcolepsy

Currently, Narcolepsy cannot be cured; however, symptoms can be managed with either the wake-promoting substance modafinil (first-line treatment) or traditional psychostimulants like amphetamines and their derivatives (if modafinil fails). Two new additions to the stimulant group include pitolisant (a selective histamine H_3 receptor reverse agonist) and solriamfetol (a selective dopamine and norepinephrine reuptake inhibitor). Sodium oxybate has proven extremely effective for reducing cataplexy, even in cases where the cataplexy was thought to be intractable. Studies also suggest that sodium oxybate helps improve sleep and relieves some of the sleepiness associated with narcolepsy. In addition, REM sleep suppressing drugs (e.g., many antidepressants) may help cataplexy. This approach capitalizes on the anticholinergic REM sleep suppressant properties of these drugs. Since cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine and protriptyline are quite effective for reducing or eliminating cataplexy. Selective serotonin reuptake inhibitors have gained popularity because they are associated with fewer side effects than the tricyclic antidepressants. The American Academy of Sleep Medicine recently released an updated guideline on treatment of central disorders of hypersomnolence (see Maski et al., 2021). Although drug therapies are the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance (if stimulants are used), and careful monitoring of refills, general health, and cardiac status.

SLEEP-RELATED BREATHING DISORDERS

Overview

Sleep-related breathing disorders include disorders along several different dimensions, including those involving (1) large airway obstruction during sleep, (2) breathing cessation resulting from central respiratory mechanisms, and (3) hypoventilation without breathing cessation. A sleep-related breathing cessation (**apnea**) is defined as a cessation of breathing for 10 seconds or more during sleep. Hypopnea is a reduction in breathing for 10 seconds or more during sleep. The 10 seconds duration is in adult patients. In the pediatric population, a respiratory event during sleep lasting longer than two times the respiratory cycle time is considered abnormal. These sleep-related breathing impairments are most often caused by airway obstruction; however, sometimes respiratory reduction results from central (brainstem) changes in ventilatory control, heart failure, or metabolic factors.

Cessation or reduced breathing during wakefulness is not intrinsically pathophysiologic. One can voluntarily hold one’s breath to avoid noxious odors. When speaking, an individual reduces airflow to the lungs. Neither of these activities constitutes dysfunction. However, when asleep, breathing cessations or reductions typically provoke CNS arousal, significant oxyhemoglobin desaturation, or both. Thus, the apnea or hypopnea ***induces*** a pathophysiologic event.

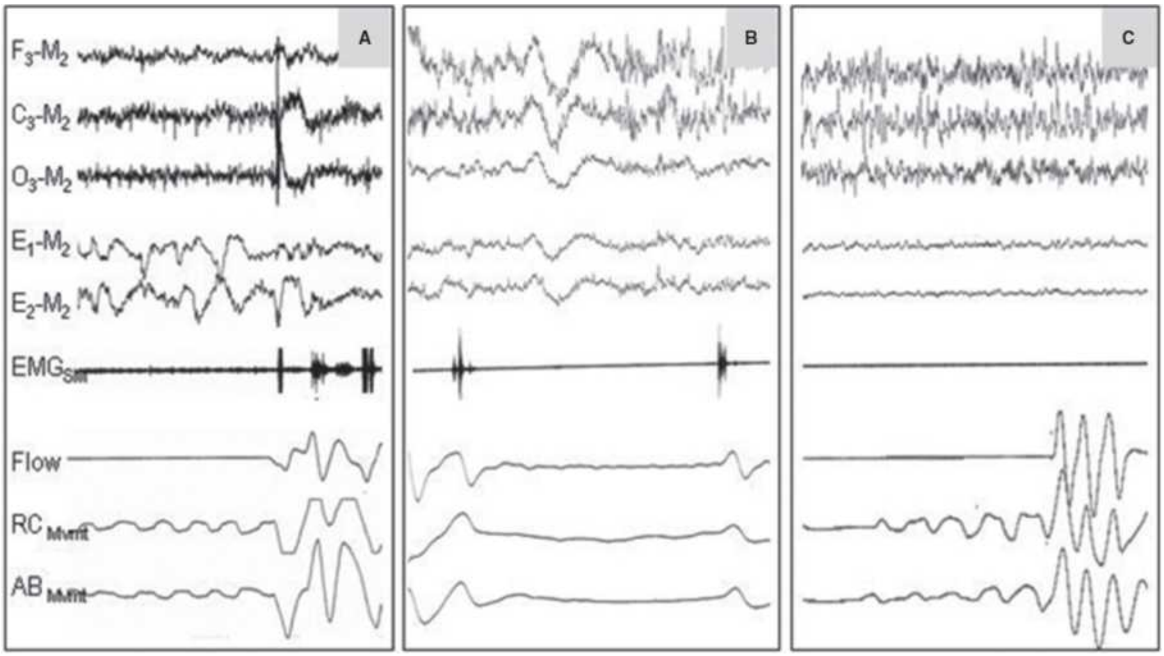

FIGURE 23–4. Polysomnographic tracings illustrating sleep apnea episodes. **Panel A** illustrates an obstructive sleep apnea, **Panel B** shows a central sleep apnea, and **Panel C** depicts a mixed sleep apnea. Note the presence of respiratory effort (rib cage and abdominal movement), notwithstanding cessation of airflow, throughout the obstructive apnea and during the latter portion of the mixed apnea. By contrast, respiratory effort is absent during the flow cessation throughout the central apnea and during the early portion of the mixed apnea. Notation: F3 (left frontal scalp derivation); M2 (right mastoid electrode location); C3 (left central scalp derivation); O3 (left occipital scalp derivation); E1 (left outer canthus eye electrode location); E2 (right outer cantus eye electrode location); EMGSM (surface electrode electromyogram from submentalis muscle); Flow (airflow measured with nasal–nasal–oral thermistors); RC Mvmt (rib cage movement measured with inductive pleythsmography); AB Mvmt (abdominal movement measured with inductive pleythsmography). (Reprinted from Hirshkowitz M, Sharafkhaneh A. Diagnostic assessment methods in adults. In: Kryger MH, Avidan AY, Berry RB, eds. *Atlas of Clinical Sleep Medicine*. 2nd ed. Elsevier Saunders; 2014:378.)

Each sleep apnea can be classified as obstructive, central, or mixed. Obstructive apnea results from airway collapse, notwithstanding continued respiratory effort. In central apnea, the breathing cessation results from decreased or absent respiratory effort. Mixed apnea typically begins with a central apnea, but when respiratory effort resumes, airway collapse prevents ventilation. Figure 23–4 illustrates obstructive, central, and mixed apnea episodes. A partial airway obstruction that produces a 4% (or more) oxyhemoglobin desaturation is scored as an obstructive hypopnea, according to Central Medicare Services (CMS) criteria. By contrast, partial airway obstruction not meeting the CMS desaturation criteria but provoking a brief CNS arousal can be scored as a respiratory effort–related arousal (RERA) according to AASM criteria. Figure 23–5 shows a polysomnographic tracing for obstructive hypopnea and RERA.

Obstructive Sleep Apnea Hypopnea (OSAH)

Diagnostic Criteria. Obstructive sleep-related breathing ranges across the spectrum from upper airway resistance syndrome to severe OSAH. **Adult Diagnostic Criteria:** An adult meets the criteria if an overnight polysomnographic sleep study or home sleep apnea testing (HSAT) shows a combined total of predominantly obstructive apnea and hypopnea of 15 (or more) per hour of sleep. However, if the patient has relevant symptoms or comorbid conditions, only 5 (or more) events per hour are required. Relevant symptoms include any of the following: hypersomnolence (given that the individual has adequate opportunity to sleep); witnessed cessation of breathing during sleep; gasping or snorting; or habitual snoring. Medicare and/or ICSD-3 also considers relevant comorbid conditions such as hypertension, mood disorder, cognitive dysfunction, coronary artery disease, stroke, congestive heart failure, atrial fibrillation, or type 2 diabetes as reasons to use the lower apnea and hypopnea criteria. ICSD also defines **Pediatric Diagnostic Criteria** as a child with overnight polysomnographic sleep showing a combined total of one (or more) obstructive apneas, mixed apneas, and hypopneas per hour of sleep. An alternative polysomnographic finding of obstructive hypoventilation (25% [or more] of total sleep time with hypercapnia [$PaCO_2$ > 50 mmHg]) in association with flattened nasal pressure tracings during inspiration. Either of these two polysomnographic findings, when associated with snoring, paradoxical movement of the chest wall and abdomen during sleep, sleepiness, behavioral or learning problems, or hyperactivity, makes the diagnosis. Recent years have seen a significant shift toward using HSAT with or without measurement of EEG and sleep stages for diagnosis of OSAH.

Comorbidities. In adults, obstructive sleep apnea is associated with many serious and chronic illnesses. A review of over four million records from the Veterans Health Administration (VHA) from 1998 to 2001 found a

2.91% (118,105) prevalence of sleep apnea in that population. Comorbid diagnoses included hypertension (60.1%), obesity (30.5%), diabetes mellitus (32.9%), cardiovascular disease including angina and myocardial infarction (27.6%), heart failure (13.5%), and stroke including transient ischemic attacks (5.7%). Psychiatric comorbidity in the sleep apnea group was significantly higher ($P < .0001$) than in the non-sleep apnea group for mood disorders, anxiety and posttraumatic stress disorder, psychosis, and dementia. There are several theories about the reason for this association. Psychiatric disorders may be a consequence of sleep apnea (and disturbed sleep and hypoxemia). Conversely, psychiatric disorders may predispose people to develop sleep disturbances such as sleep apnea. Pediatric obstructive sleep apnea is associated with neurobehavioral and cardiovascular problems. Obesity and growth abnormalities are also reported.

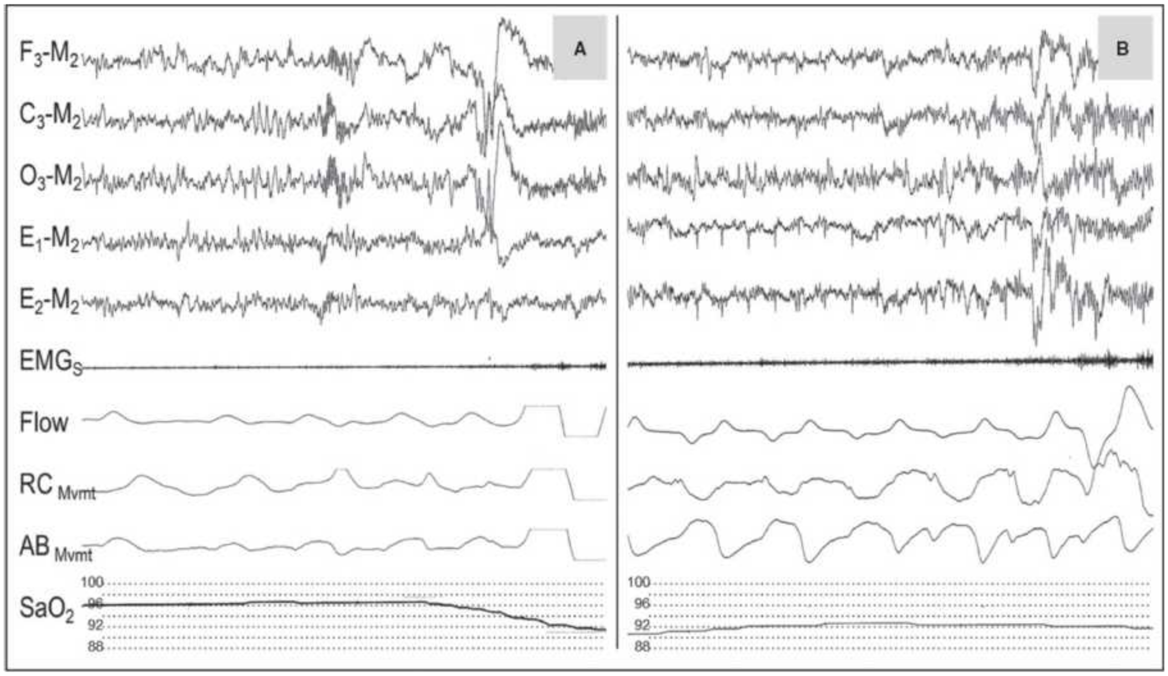

FIGURE 23–5. Sleep hypopnea and respiratory effort–related arousal (RERA) episodes. **Panel A** illustrates an obstructive hypopnea, **Panel B** shows a RERA. Note the presence of respiratory effort (rib cage and abdominal movement), notwithstanding reduced of airflow. The hypopnea episode is accompanied by significant oxyhemoglobin desaturation as the event progresses. By contrast, the RERA does not provoke desaturation; however, a CNS arousal occurs followed by increasing ventilation. Notation: F3 (left frontal scalp derivation); M2 (right mastoid electrode location); C3 (left central scalp derivation); O3 (left occipital scalp derivation); E1 (left outer canthus eye electrode location); E2 (right outer cantus eye electrode location); EMGSM (surface electrode electromyogram from submentalis muscle); Flow (airflow measured with nasal–nasal–oral thermistors); RC Mvmt (rib cage movement) measured with inductive pleythsmography; AB Mvmt (abdominal movement) measured with inductive pleythsmography; SaO_2 (pulse oximetry) shows oxygen saturation percentage. (Reprinted from Hirshkowitz M, Sharafkhaneh A. Polysomnography and home sleep test assessment methods in adults. In: Kryger MH, Avidan AY, Berry RB, eds. *Atlas of Clinical Sleep Medicine*, 3rd ed. Elsevier; 2024:447.)

Treatments. Interventions available for treating OSAH include (a) positive airway pressure (PAP), (b) oral appliances, (c) positional therapy, (d) surgical intervention, and (e) weight loss. Medication therapies have been tried for OSA but without success. Medroxyprogesterone acetate was originally thought to be helpful but is seldom used now. Likewise, tricyclic antidepressants sometimes decrease apnea severity by reducing REM sleep, the stage of sleep in which obstructive apnea is usually more frequent. Theophylline was reported to reduce apnea, but further study is needed. There were also animal studies suggesting mirtazapine and similar serotonin presynaptic affecting compounds improved breathing; however, studies in humans were disappointing. The only medications approved for use in patients with OSAH are the wake promoting substances including modafinil, armodafinil, and solriamfetol. These stimulant agents, however, do nothing to treat the pathophysiology of airway occlusion but rather are used as an adjunct for treating the residual sleepiness that persists in about 8% to 12% of patients who are otherwise well treated with and adequately use PAP therapy.

POSITIVE AIRWAY PRESSURE (PAP). Currently, PAP is the preferred treatment for OSAH. The PAP apparatus consists of a fan-driven blower, a nasal mask or oronasal interface, and tubing connecting the two. The airflow through the interface (usually a mask or nasal pillows) provides a positive pressure that offsets oropharyngeal collapse produced by inspiratory negative thoracic pressure. In this manner, it acts as a pneumatic splint, thereby maintaining the airway. Even the most severe sleep apnea can usually be alleviated when the pressure is properly titrated. Results are often dramatic. PAP devices come in several varieties. The most common systems provide a pre-set continuous positive airway pressure (CPAP). For individuals who find it difficult to exhale against continuous pressure, bi-level positive airway pressure (BPAP) may provide a solution. BPAP devices have different inspiratory and expiratory pressure settings. More recently, systems that sense the patient’s changes in airway resistance and automatically adjust the positive airway pressure (APAP) have been gaining popularity. Such APAP systems should theoretically be able to adapt to changes in pressure requirements produced by sleep deprivation, medications, weight change, sleep depth, illness, and aging. Finally, timed bi-level and servo-ventilation systems have also been developed but fall into the category of noninvasive positive pressure ventilation (NIPPV) systems that are more appropriate for treating other pulmonary diseases and breathing problems in neuromuscular diseases. PAP therapies’ tremendous efficacy and remarkable safety have made it the standard of care for patients who can tolerate sleeping with the machine (see Fig. 23–6). The major therapeutic challenge is utilization. Patient education and systematic follow-up are crucial. When problems with the interface, the pressure, nasal stuffiness, and other barriers to routine, nightly use arise, they must be remedied quickly to assure therapeutic adherence. The use of reminders improves PAP utilization. Current PAP technology allows telemonitoring of PAP use and adjustment of therapy if needed. When used properly, PAP therapy's success has rendered surgical intervention a secondary option, resorted to mainly after PAP failure, rejection, or nonadherence.

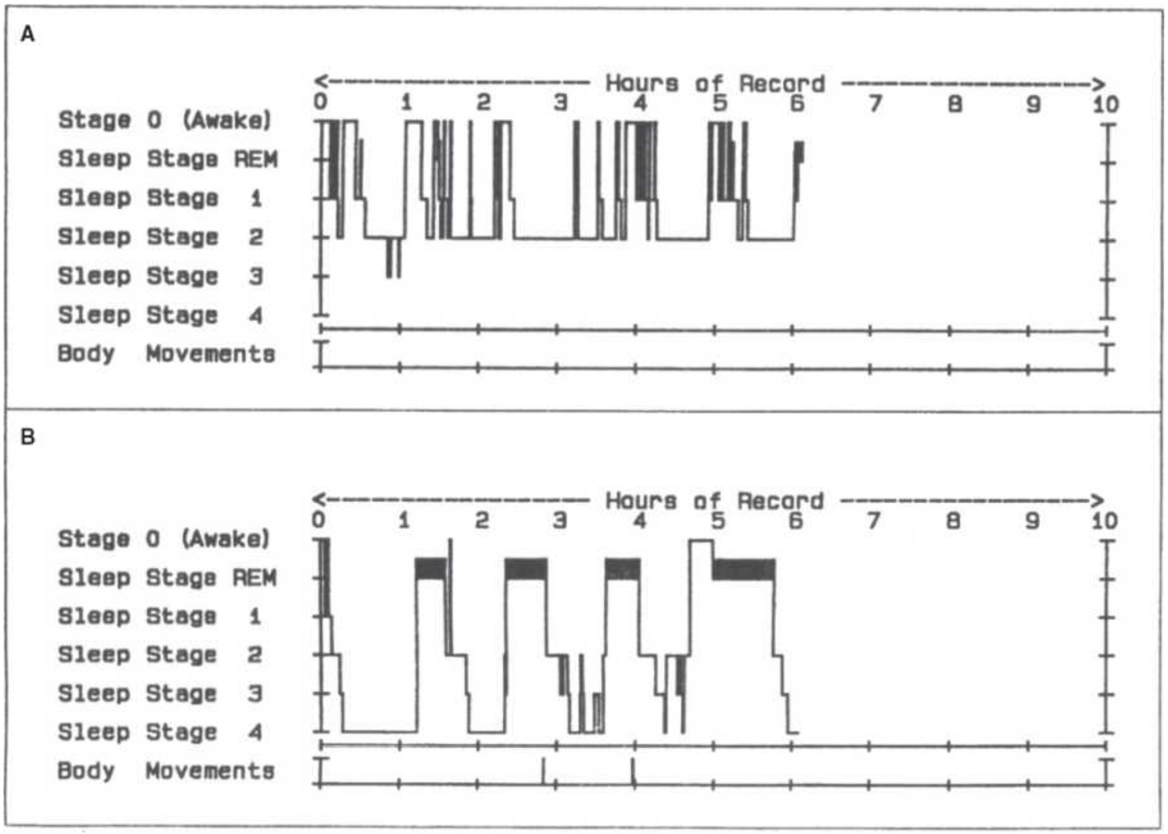

FIGURE 23–6. Sleep histogram showing CPAP-related sleep improvement. Sleep stage histogram illustrating the immediate, dramatic improvement in sleep architecture produced by treating obstructive sleep apnea with continuous positive airway pressure (CPAP) therapy. **Panel A** illustrates the abnormal sleep pattern on a night when the patient had more than 200 episodes of obstructive sleep apnea. Sleep is disturbed by frequent awakenings while REM and slow-wave (stages 3 and 4) sleep are nearly absent. **Panel B** shows data from the same patient being treated with CPAP on the next night. Normalization of sleep continuity with a massive rebound in REM and slow-wave sleep is evident.

ORAL APPLIANCE. Oral appliances represent another therapeutic option that is gaining popularity. A variety of oral appliances have also been developed to treat snoring and can benefit patients with mild-to-moderate

OSAH. The general approach is to manipulate the position of the mandible, lift the palate, and/or retain the tongue. Randomized trials indicate that some oral appliances sufficiently improve airway patency. Use of a titratable appliance is recommended over non–custom-made devices. However, in patients with severe OSAH, improvement does not always reach satisfactory levels; therefore, follow-up evaluations are critically important.

POSITIONAL THERAPY. In some cases, obstructed breathing occurs only when the patient sleeps supine. In such situations, preventing patients from sleeping on their backs may produce beneficial results. Tennis balls sewn onto or placed into pockets on the back of the nightshirt, foam wedges, or devices that alarm when the patient is supine may accomplish this goal. Although such interventions are found useful in clinical practice, large-scale systematic clinical trials are needed.

SURGICAL INTERVENTION. Aggressive surgical treatments evolved soon after OSAH's pathophysiologic and potentially life-threatening consequences were recognized. The earliest surgical intervention was designed to create a patent airway; thus, in the late 1970s tracheostomies were performed on individuals with severe apnea. There is little doubt that tracheostomy succeeds in creating an airway. Although no longer the preferred treatment, it remains a standard against which newer, more refined therapies are judged. Second-generation surgical approaches attempted to correct airway obstructions and malformations. Early studies of uvuolopalatopharyngoplasty (UPPP) suggested that modification of the soft palate effectively relieved most sleep apnea. Later follow-up results were less impressive. Approximately 30% to 50% of patients with sleep apnea benefit from UPPP. These patients are likely those with oropharyngeal obstruction; thus, careful attention to selection criteria presumably improves outcome. However, if obstruction occurs in the posterior airway space (PAS), maxillomandibular surgery may be appropriate. In retrognathic patients or patients with cephalometrics revealing compromised PAS, moving the jaw forward can achieve impressive normalization of breathing during sleep. Drug-induced sleep endoscopy (DISE) may assist in better identifying the site(s) of obstruction before planning surgical intervention, including multilevel or stepwise upper airway surgery. Upper airway stimulation by implanting a unilateral hypoglossal nerve stimulator is a new addition to surgical intervention for the management of OSAH.

A recently approved implantable device acts by stimulating the hypoglossal nerve, which produces tongue protrusion, opens the upper airways, and reduces the severity of sleep apnea. The device, called Inspire, is FDA approved and is placed by an ENT specialist.

WEIGHT LOSS. Weight loss is known to help many patients. However, because losing weight and maintaining weight loss is difficult and unreliably achieved, the prudent clinician should recommend weight loss but rely on other therapies.

Central Sleep Apnea

The key characteristic linking the various central sleep apnea syndromes is that breathing cessations are not provoked by upper airway flow limitations or obstructions. Breathing diminishes or stops due to a reduction or lack of respiratory effort. Several different etiologies can produce central respiratory events, including heart failure, high altitude, brainstem lesions, metabolic conditions, CNS depressants, congenital abnormalities, and PAP treatment.

Diagnostic Criteria. For diagnosing Central Sleep Apnea, DSM-5-TR requires polysomnographic evidence of five or more central apneas per hour of sleep. Also, the disorder must not be better explained by another concurrent sleep disorder. Clinicians should specify whether the central apnea is associated with (a) Cheyne–Stokes breathing, (b) comorbid opioid use, or (c) no evidence of airway obstruction. ICSD-3 describes eight diagnostic entities, as follows: (1) Central Sleep Apnea with Cheyne–Stokes Breathing, (2) Central Apnea Due to a Medical Disorder without Cheyne–Stokes Breathing, (3) Central Sleep Apnea Due to High Altitude Periodic Breathing, (4) Central Sleep Apnea Due to Medication or Substance, (5) Primary Central Sleep Apnea, (6) Primary Central Sleep Apnea of Infancy, (7) Primary Central Sleep Apnea of Prematurity, and (8) Treatment-Emergent Central Sleep Apnea. These conditions are described in the Central Apnea Subtypes section below.

Central Apnea Subtypes Described in ICSD-3

CENTRAL SLEEP APNEA WITH CHEYNE–STOKES BREATHING. Cheyne–Stokes Breathing is characterized by a unique breathing pattern consisting of prolonged hyperpnea events during which tidal volume gradually waxes and wanes in a crescendo–decrescendo fashion. The hyperpnea events alternate with apnea and/or hypopnea episodes that are associated with reduced ventilatory effort. This pattern is most common in older men with congestive heart failure or stroke. As with Primary Central Sleep Apnea, the patients present with daytime sleepiness or fatigue, insomnia, and awakening with shortness of breath. Polysomnography reveals five or more central apnea and hypopnea episodes per hour of sleep.

CENTRAL APNEA DUE TO A MEDICAL DISORDER WITHOUT CHEYNE–STOKES BREATHING. This form of central sleep apnea is usually caused by a brainstem lesion associated with a wide range of variable etiologies. Cardiac and renal disorders can also cause central apnea. Diagnostic criteria require a polysomnographically verified rate of five or more central apneas and hypopneas per hour of sleep.

CENTRAL SLEEP APNEA DUE TO HIGH ALTITUDE PERIODIC BREATHING. Central apnea at sleep onset is universal at elevations above 7,600 m but can occur at 1,500 m in some individuals (especially with a recent or rapid ascent). Periods of central apnea alternate with periods of hyperpnea in a 12- to 34-second cycle. This is an extension of normal respiratory control at sleep onset, where medullary pH receptors diminish their set-point and require lower pH to respond. At high altitudes, hyperventilation causes a hypocapnic alkalosis that reduces ventilation during sleep. Sleep architecture may suffer with increased duration in stages one and two and less slow wave sleep. REM sleep may not be affected. This condition can be treated with acetazolamide which lowers serum pH and increases the respiratory drive. Acetazolamide side effects include metabolic acidosis, electrolyte imbalance, anaphylaxis, Stevens–Johnson syndrome, toxic epidermal necrolysis, and agranulocytosis. Common reactions include but are not limited to fatigue, anorexia, taste changes, polyuria, diarrhea, melena, tinnitus, and photosensitivity.

CENTRAL SLEEP APNEA DUE TO MEDICATION OR SUBSTANCE. Central apnea episodes can be provoked by various drugs or drug combinations, most notably, long-acting opiates. An essential objective diagnostic criterion is a central apnea index (number of episodes per hour) of five or more per hour of sleep.

PRIMARY CENTRAL SLEEP APNEA. This is an idiopathic form of central sleep apnea. Patients typically have low normal $PaCO_2$ while awake and have a high ventilatory response to CO_2. They may present with daytime sleepiness, insomnia, and/or awakening with shortness of breath. Respiratory cessations during sleep occur independently of ventilatory effort. Polysomnography reveals five or more central apneas per hour of sleep.

PRIMARY CENTRAL SLEEP APNEA OF INFANCY. This form of central sleep apnea involves prolonged apneas or hypopneas with concomitant hypoxemia, bradycardia, or both. This condition afflicts preterm neonates presumably because their brainstems are not fully developed. The condition may be exacerbated by other medical problems that further compromise the infant's physiologic and developmental status.

PRIMARY CENTRAL SLEEP APNEA OF PREMATURITY. Central apnea, cyanosis, significant oxyhemoglobin desaturation, or bradycardia may be detected during postnatal hospital monitoring in infants less than 37 weeks conceptual age. Polysomnography or home monitoring must show either (i) recurrent 20 second or longer central apneas or (ii) periodic breathing for 5%, or more, of total sleep time.

TREATMENT-EMERGENT CENTRAL SLEEP APNEA. In patients with obstructive sleep apnea who are treated with PAP, central apnea episodes sometimes emerge. If the central apnea persists over time and lowering the pressure permits obstructions to re-occur (i.e., lower pressures are not adequate to treat the obstructive apnea), the patient is considered to have treatment-emergent central sleep apnea.

Sleep-Related Hypoventilation

Sleep-related hypoventilation is commonly associated with chronic obstructive pulmonary disease, obesity, and neuromuscular disease. However, other comorbid medical conditions may contribute. ICSD-3 differentiates hypoventilation disorders from hypoxemia disorders and further subdivides each. In hypoventilation disorders, ICSD-3 includes (1) obesity hypoventilation syndrome, (2) congenital central alveolar hypoventilation syndrome, (3) late-onset central hypoventilation and hypothalamic dysfunction, (4) idiopathic central alveolar hypoventilation, (5) sleep-related hypoventilation due to a medication or substance, and (6) sleep-related hypoventilation due to a medical disorder. ICSD-3 also lists (7) sleep-related hypoxemia as a separate nosologic entity. Snoring and catathrenia (sleep-related groaning) are considered isolated symptoms and normal variants.

Diagnostic Criteria. Polysomnography must demonstrate either (a) episodes with elevated CO_2 levels and decreased respirations and/or (b), if CO_2 is not monitored, episodes of persistently low oxyhemoglobin levels that are not provoked by apnea or hypopnea. Clinicians should specify if the hypoventilation is attributable to (i) congenital central alveolar hypoventilation, (ii) comorbid sleep-related hypoventilation (e.g., COPD), or if it is (iii) idiopathic hypoventilation. Severity should also be specified related to evidence of relevant diseases (e.g., right heart failure) or blood gasses (if available).

CIRCADIAN RHYTHM SLEEP–WAKE DISORDERS

This collection of sleep disorders shares the same basic underlying etiology: desynchrony between an individual’s internal circadian biologic clock and the desired sleep–wake cycle. The circadian (circa+dias, approximately one day) pacemaker is located in the suprachiasmatic nucleus (SCN). SCN firing oscillates with an almost sinusoidal pattern, the period of which is 24 hours, and the output correlates with the daily fluctuations in core body temperature. SCN firing patterns persist even in *isole* preparations. Mismatched circadian clock and desired schedules can arise from improper phase relationships between the two, travel across time zones, or dysfunctions in the basic biologic rhythm. DSM-5-TR provides six specific subtype coding for disorders listed as separate ICSD-3 diagnostic entities. Jet Lag Disorder is also listed in ICSD-3 but not in DSM-5-TR.

Diagnostic Criteria

To diagnose a Circadian Sleep–Wake Disorder, an individual must (1) have an alteration in or misalignment between their endogenous circadian rhythm and their desired sleep–wake schedule; (2) the alteration or misalignment must disrupt sleep-producing insomnia and/or hypersomnolence, and (3) this circumstance must either elicit significant distress or social, occupational, or other functional impairment. The clinician should specify if the Circadian Sleep–Wake Disorder subtype constitutes (a) Delayed sleep phase type, (b) Advanced sleep phase type, (c) Irregular sleep–wake type, (d) Non–24-hour sleep–wake type, (e) Shift work type, or (f) Unspecified type. The diagnosis should also indicate whether the problem is (a) **episodic** with symptoms lasting 1 month or more but less than 3 months; (b) **persistent** with symptoms lasting 3 months or more; or (c) **recurrent** with two (or more) episodes within a 1-year period.

Circadian Rhythm Sleep–Wake Disorder Subtypes

Delayed Sleep Phase Type. The Delayed Sleep Phase circadian disorder occurs when the biologic clock runs slower than 24 hours or is shifted later than the desired schedule. This produces a phase delay in the sleepiness-alertness cycle. Individuals with a delayed sleep phase are more alert in the evening and early nighttime, stay up later, and are more tired in the morning. These individuals are commonly referred to as *night owls*.

Advanced Sleep Phase Type. The Advanced sleep phase is when the circadian rhythm cycle is shifted earlier. Therefore, the sleepiness cycle is advanced with respect to clock time. Individuals with advanced sleep phase are drowsy in the evening, want to retire to bed earlier, awaken earlier, and are more alert in the early morning. Individuals with this pattern of advanced sleep phase are sometimes called *early birds or larks* (sometimes jokingly called *surgeons* in the medical center).

Irregular Sleep–Wake Type. The irregular sleep–wake pattern occurs when the circadian rhythm is absent or pathologically diminished. The sleep–wake pattern is temporally disorganized, and the timing of sleep and wakefulness is unpredictable. Individuals with this condition will have a normal amount of sleep during a 24-hour period; however, it will be fragmented into three or more episodes that occur irregularly. Long daytime naps and inappropriate nocturnal wakefulness will occur. Except in unusual circumstances, activities of daily life are significantly impaired.

Non–24-Hour Sleep–Wake Type. A patient may develop this type of circadian rhythm disorder when the circadian sleep–wake pacemaker has a cycle length greater or less than 24 hours and is not reset each morning. Under normal circumstances, resynchronization of our circadian rhythm occurs daily in response to the light-dark cycle. Problems occur incrementally when internal and environmental clocks become more and more out of phase. If the circadian clock's period is longer than 24 hours and does not reset each day, the patient experiences progressively worsening sleep-onset insomnia and daytime sleepiness. Sleep problems peak when circadian and environmental clocks are 12 hours out of phase and then begin to lessen, emulating progressively resolving advanced sleep phase. Eventually, the clocks correlate, and the sleep–wake cycle is normal for a few days, after which the insomnia–hypersomnia cycle begins again. For this reason, non–24-hour sleep–wake disorder has been called periodic insomnia and periodic excessive sleepiness.

Shift Work Type. Many service industries require 24-hour operation (e.g., transportation, health care). Similarly, as our cultures became more capital intensive, mining and manufacturing became around-the-clock enterprises. The number of individuals doing shift work has been increasing steadily for decades. Shift workers commonly suffer from insomnia, excessive sleepiness, or both. Some individuals require only a short time to adjust to a shift change, while others have great difficulty. Frequent shift rotation adds to the problems. Also, to meet social demands, shift workers will often adopt a non-shifted sleep–wake schedule on weekends and holidays. Even those individuals who try to stay shifted usually retain an unshifted circadian rhythm. The result can be severe insomnia when attempting to sleep and excessive sleepiness when attempting to remain awake. The result is profound sleep deprivation as circadian rhythm continues to be poorly entrained to the sleep–wake schedule. The natural low point in the normal sleep–wake rhythm occurs at approximately 3:00 to 5:00 A.M. Interestingly, this is precisely the time frame during which transportation and industrial accidents commonly occur as a direct consequence of sleepiness.

Jet Lag (not included in DSM-5-TR). With the advent of high-speed air travel, an induced desynchrony between circadian and environmental clocks became possible. Thus, the term jet lag came into use. When an individual rapidly travels across many time zones, they induce either a circadian phase advance or a phase delay, depending upon the direction of travel. Typically, one or two time zone translocations will not produce a sustained problem; however, overseas travel can be marked by great difficulty in adjusting one's sleep–wake routine. Individuals who frequently travel for business can find themselves quite impaired at the time they need to make important decisions. Furthermore, "owls" will experience greater difficulty adjusting to eastward travel because resynchronization requires phase advance. Similarly, larks theoretically will have more difficulty with westward travel. The number of time zones crossed is a critical factor. Normally, healthy individuals can easily adapt to 1- to 2-time zone changes per day; therefore, natural adjustment to an 8-hour translocation may take 4 or more days.

Circadian Rhythm Sleep–Wake Disorder Unspecified Type. During illnesses that keep patients bedridden, during hospitalizations, and in some forms of dementia, individuals often sleep *ad lib.* The resulting chaotic sleep–wake pattern adversely affects the circadian rhythm. The breakdown in the sleep–wake cycle may be further exacerbated by medication with sedative properties. Sleep in patients in the ICU is disturbed by noise, light, and the therapeutic and monitoring procedures being performed. The resulting disorganized sleep–wake pattern can produce a significant sleep disorder. Additionally, abuse of recreational street drugs (e.g., methamphetamine and ecstasy) is associated with individuals remaining awake overnight or continuously for several days at a time. These episodes of prolonged wakefulness ultimately produce periods of profound hypersomnia.

Treating Circadian Rhythm Sleep–Wake Disorders

Under normal circumstances, the internal circadian pacemaker is reset each day by bright light, social cues, stimulants, and activity. In cases where these factors fail to re-entrain the circadian rhythm, circadian sleep–wake disorders occur.

Light Therapy. Research indicates that light exposure can reset the circadian pacemaker. This seems especially the case when the light is bright (greater than ten thousand lux) or in the blue spectrum. The biologic clock can be reset with precise timing of bright light exposure. Exposure to light modifies the set-point of the biologic clock. Using core body temperature as a physiologic marker, one can use bright lights to produce phase delay when presented before the temperature nadir. By contrast, light exposure after temperature nadir evokes phase advance. The closer one presents light to the point of inflection (temperature nadir), the more robust the response in altering the cycle. Thus, early morning bright light therapy can be used to phase advance individuals with delayed sleep phase syndrome. Similarly, exposure to bright light in the evening can help patients with advanced sleep phase syndrome. More recently, it was discovered that the blue spectrum of light is the crucial ingredient in phase setting and shifting. Therefore, blue light exposure (or limitation with blue-blocking eyewear) at specific times can provide therapeutic benefits. Clinicians increasingly rely on light therapy to shift circadian sleep–wake rhythms of individuals with delayed and advanced sleep phases, shift workers, astronauts, and individuals experiencing jet lag.

Medication. Administering melatonin to individuals who are blind from birth successfully entrains their circadian sleep–wake rhythm. Researchers posit that melatonin secretion acts as the biologic substrate for the internal circadian oscillator. Under normal circumstances, melatonin levels begin to rise at dusk and remain elevated until dawn. Bright light suppresses the release of melatonin. Melatonin, in a sense, is the signal of darkness in the brain. As such, it can be used clinically to manage sighted patients with disturbed sleep-wake cycles. Melatonin is available over the counter in the United States. Prescription synthetic melatonin agonists (ramelteon and tasimelteon) are also available (FDA approved for treating patients with sleep-onset insomnia). A 2-mg sustained-release melatonin (Circadin) is available in many European countries, Australia, and some places in Asia. Interestingly, the wake-promoting compound modafinil is FDA approved for treating sleepiness in patients with shift work type circadian rhythm sleep–wake disorder.

Chronotherapy. Chronotherapy involves progressively phase delaying a person until the circadian oscillator is synchronized with the desired sleep-wake schedule. Most young and middle-aged adults have a propensity to progressively phase delay their circadian sleep–wake rhythm anyway. Thus, phase delaying each night by 2 or 3 hours is thought to be easier than phase advancing because it capitalizes on a natural tendency. Halting the phase delay at the appropriate moment and maintaining the desired synchrony can be challenging. The patient also has to cope with an odd sleep-wake schedule for the better part of a week during therapy (which can interfere with school or work). For these reasons, the development of light therapy and pharmacologic interventions has overshadowed chronotherapy in the past two decades.

PARASOMNIAS (AND SLEEP-RELATED MOVEMENT DISORDERS)

DSM-5-TR includes only three of the ten specific parasomnias described in ICSD-3. Furthermore, DSM-5-TR includes Restless Legs Syndrome (RLS) as a parasomnia, while in ICSD-3, it is classified as one of the seven specific Sleep-Related Movement Disorders.

Parasomnias are sometimes referred to as disorders of partial arousal. In general, parasomnias are a diverse collection of sleep disorders characterized by physiologic or behavioral phenomena that occur during or are potentiated by sleep. One conceptual framework posits many parasomnias as overlap or intrusion of one basic sleep–wake state into another. Wakefulness, NREM sleep, and REM sleep can be characterized as the three basic states that differ in their neurologic organization. During wakefulness, both the body and brain are active. In NREM sleep, both the body and brain are inactive. REM sleep, however, pairs an atonic body with an active brain (capable of creating elaborate dream fantasies). Regional cerebral blood flow, MRI, and other imaging studies confirm increased brain activation during REM sleep. It certainly appears that in some parasomnias, there are state boundary violations. For example, arousal disorders (sleepwalking and sleep terrors) involve momentary or partial wakeful behaviors suddenly occurring in NREM sleep. Similarly, the ICSD-3 nosologic entity Isolated Sleep Paralysis is the persistence of REM sleep atonia into the wakefulness transition, while REM sleep behavior disorder is the failure of the mechanism creating paralytic atonia such that individuals literally act out their dreams.

The occurrence frequency of significant parasomnias varies. Clinical significance relates more to the medical consequences or the patient’s evoked level of distress than to how often the abnormal events occur. Parasomnias’ irregularities in occurrence make them difficult to document in the sleep laboratory. Sleep studies, however, are indicated for ruling out whether the unusual behavior is secondary to a seizure disorder or a sleep-related breathing disorder.

Non-Rapid Eye Movement (NREM) Sleep Arousal Disorders

Sleepwalking. Sleepwalking in its classic form, as the name implies, is a condition in which an individual arises from bed and ambulates without fully awakening. Sometimes called somnambulism, individuals can engage in a variety of complex behaviors while unconscious. Sleepwalking usually occurs during NREM slow wave sleep and characteristically begins toward the end of the first or second slow wave sleep episodes. Sleep deprivation and interruption of slow wave sleep appear to exacerbate, or even provoke, sleepwalking in susceptible individuals. Sleepwalking episodes may range from sitting-up and attempting to walk to conducting an involved sequence of semi-purposeful actions. The sleepwalker can often successfully interact with the environment (e.g., avoiding tripping over objects in his path). However, the sleepwalker will often interact with the environment inappropriately, which sometimes results in injury (e.g., stepping out of an upstairs window or walking into the roadway). There are cases in which sleepwalkers have committed acts of violence. An individual who is sleepwalking is difficult to awaken. Once awake, the sleepwalker will usually appear confused. It is best to gently attempt to lead sleepwalkers back to bed rather than attempting to awaken them by grabbing, shaking, or shouting. In their confused state, the sleepwalker may think they are being attacked and may react violently to defend themselves. Sleepwalking in adults is rare, has a familial pattern, and may occur as a primary parasomnia or secondary to another sleep disorder (e.g., sleep apnea). By contrast, sleepwalking is very common in children, with peak prevalence between 4 and 8 years of age. After adolescence, it usually disappears spontaneously. Nightly to weekly sleepwalking episodes associated with physical injury to the patient and others are considered severe.

Sleep Terrors. A sleep terror is characterized by a sudden arousal with intense fearfulness. They may begin with a piercing scream or cry (see Fig. 23–7). Autonomic and behavioral correlates of fright typically mark the experience. An individual experiencing a sleep terror usually sits up in bed, is unresponsive to stimuli, and is confused or disoriented if awakened. Vocalizations may occur, but they usually are incoherent. Notwithstanding the intensity of these events, amnesia for the episodes usually occurs. Like sleepwalking, these episodes usually arise from slow wave sleep. Fever and CNS depressant withdrawal potentiate sleep terror episodes. Unlike nightmares in which an elaborate dream sequence unfolds, sleep terrors may be devoid of images or contain only fragments of very brief but frighteningly vivid and sometimes static images. Sometimes called *Pavor nocturnus*, incubus, or night terror, a familial pattern has been reported. Like other slow wave sleep parasomnias, sleep deprivation can provoke or exacerbate sleep terrors. Psychopathology is seldom associated with sleep terrors in children; however, a history of a traumatic experience or frank psychiatric problems is often comorbid in adults with this disorder. Severity ranges from less than once per month to an almost nightly occurrence (with injury to the patient or others).

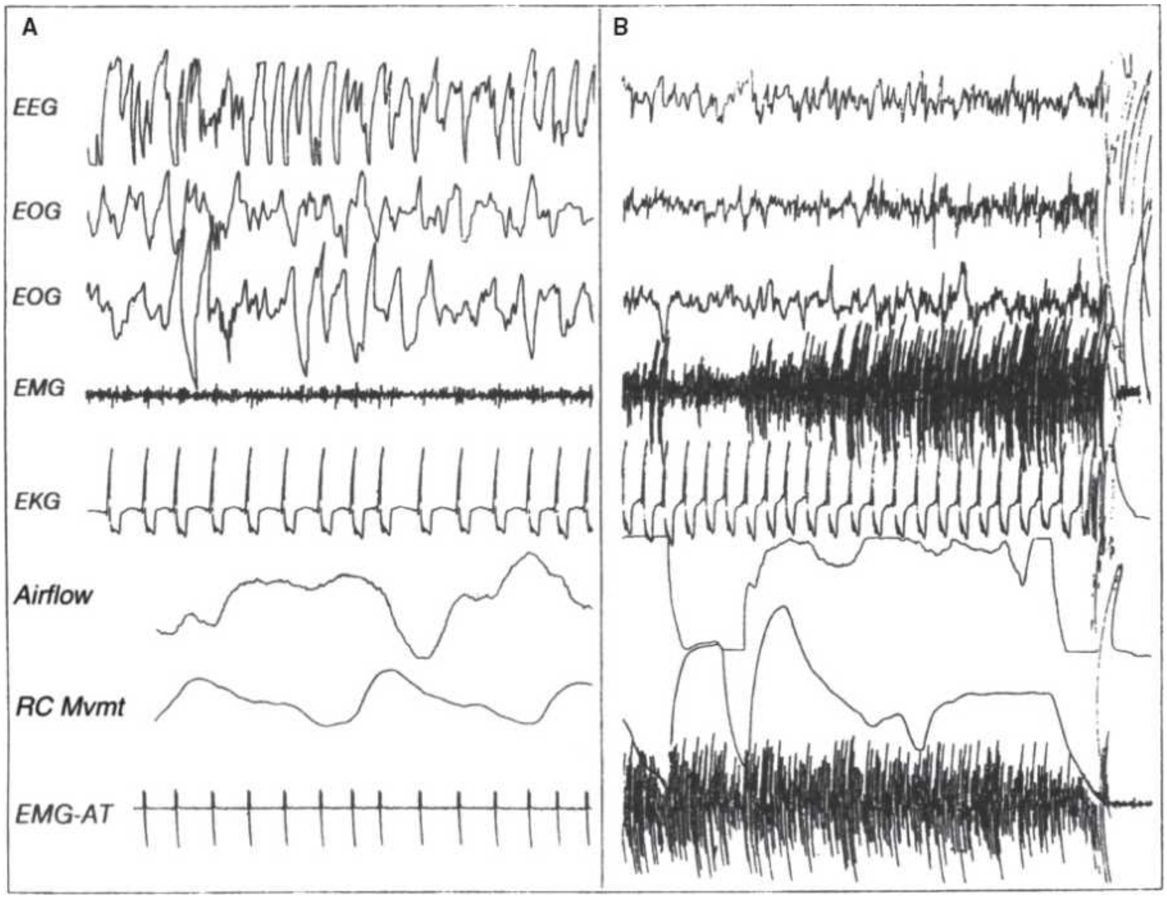

FIGURE 23–7. Polysomnographic tracing illustrating a sleep terror. **Panel A** shows approximately 14 seconds of tracing occurring immediately before the sleep terror. Prominent EEG slow-wave activity and other characteristics of stage 4 sleep are seen. **Panel B** shows the awakening, accompanied by tachycardia and movement. EEG activity is ambiguous and the patient eventually disconnected his electrodes as he thrashed about in bed (visible at far right of figure). Although the patient was screaming and greatly agitated, there was no report of dreaming. In the morning, there was little recollection of anything having occurred during the night.

Diagnostic Criteria. For Sleepwalking, DSM-5-TR requires repeated episodes of rising from bed and walking. The sleepwalker usually has a blank expression, is generally nonresponsive, and is difficult to awaken. For Sleep Terror, there must also be recurrent episodes where the individual awakens with intense fear and autonomic signs of distress. The patient is typically so panicked as to be inconsolable.

The clinician should specify if the NREM Parasomnia is: (a) sleepwalking, (b) sleepwalking type with sleep-related eating, (c) sleepwalking type with sleep-related sexual behavior (sexsomnia), or (d) sleep terror type.

Nightmare Disorder

Nightmares are frightening or terrifying dreams. Sometimes called dream anxiety attacks, they can produce sympathetic activation and ultimately awaken the dreamer. Nightmares occur in REM sleep and usually evolve from a long, complicated dream that becomes increasingly frightening. Having aroused to wakefulness, the dream content is typically remembered (in contrast to sleep terrors). Some nightmares are recurrent, and reportedly when occurring in association with posttraumatic stress disorder, they may be recollections of actual events. Common in children ages 3 to 6 (prevalence estimates range from 10% to 50%), nightmares are rare in adults (1% or less). Frequent and distressing nightmares are sometimes responsible for insomnia because the individual is afraid to sleep. In Freudian terms, the nightmare is an example of the failure of the dream process that defuses the emotional content of the dream by disguising it symbolically, thus preserving sleep. Most patients afflicted with nightmares are free from psychiatric conditions. Nonetheless, individuals at risk for nightmares include those with schizotypal, borderline, and schizoid personality disorders, as well as schizophrenia. Hartmann (1998) posits that nightmares are more common in individuals with “thin boundaries” who are open, trusting, and often have creative or artistic inclinations. Having thin boundaries makes these individuals more vulnerable; furthermore, they may be at risk for schizophrenia. Traumatic events are known to induce nightmares, sometimes immediately but at other times delayed. The nightmares can persist for many years. Several medications are known to sometimes provoke nightmares, including L-DOPA, beta-adrenergic blockers, and withdrawal from REM suppressant medications. Finally, drug or alcohol abuse is associated with nightmares.

Frequently occurring nightmares often produce a “fear of sleeping” type of insomnia. In turn, the insomnia may provoke sleep deprivation, which is known to exacerbate nightmares. In this manner, a vicious cycle is created. Treatment using behavioral techniques can be helpful. Universal sleep hygiene, stimulus control therapy, lucid dream therapy, and cognitive therapy reportedly improve sleep and reduce nightmares. BZD and BZRAs are sometimes used as treatment. Additionally, evidence for the use of prazosin, a central nervous system alpha-1 receptor antagonist, in the treatment of PTSD-related nightmares is growing. Prazosin significantly increased total sleep time and REM sleep time and significantly reduced trauma-related nightmares and distressed awakenings.

Rapid Eye Movement Sleep Behavior Disorder

REM sleep behavior disorder involves a failure of the patient to have atonia (sleep paralysis) during stage REM sleep. The result is that the patient literally enacts their dreams. Under normal circumstances, the dreamer is immobilized by REM-related hypopolarization of alpha and gamma motor neurons. Without this paralysis or with intermittent atonia, punching, kicking, leaping, and running from bed during attempted dream enactment occur. The activity has been correlated with dream imagery, and unlike during sleepwalking, the individual seems unaware of the actual environment but rather is acting on their dream sensorium. Thus, a sleepwalker may calmly go to a bedroom window, open it, and step out. By contrast, a person with REM sleep behavior disorder would more likely dive through the window thinking it is a dream-visualized lake. Patients and bed partners frequently sustain an injury, sometimes serious (e.g., lacerations, fractures). A wide variety of drugs and comorbid conditions can precipitate or worsen RBD (see the section on Parasomnia Due to Drug or Substance Use and Parasomnia Due to Medical Conditions). In animals, presumed RBD can be produced with bilateral perilocus coeruleus lesions. In humans, there is a suggestion that RBD may result from diffuse hemispheric lesions, bilateral thalamic abnormalities, or brainstem lesions. Clonazepam has been used successfully to treat RBD.

Restless Legs Syndrome

RLS is characterized by the irresistible urge to move the legs when at rest or while trying to fall asleep. Patients often report crawling feelings in their legs. Moving the legs or walking around helps alleviate the discomfort (see Fig. 23–8). Thus, as individuals lie in bed and relax, they are disturbed by these sensations. They then move their legs and again try to fall asleep. This cycle sometimes continues for hours and results in profound insomnia.

Diagnostic Criteria. For the diagnosis of RLS, DSM-5-TR requires the criteria shown in Table 23–5.

An NIH workshop established criteria for the diagnosis of RLS (see Table 23–6). Uremia, neuropathies, and iron and folic acid deficiency anemias can produce secondary RLS. RLS is also associated with fibromyalgia, rheumatoid arthritis, diabetes, thyroid diseases, and chronic obstructive pulmonary disease. Detailed history and physical exam are an important part of the RLS work up. In addition, ferritin levels should be checked.

Pharmacologically, the dopaminergic agonists pramipexole, rotigotine, and ropinirole and gabapentin encarbil (extended-release form) are FDA approved and represent the treatments of choice. These four compounds have evidence-based support. Nonetheless, other agents used to treat RLS include dopamine precursors (e.g., levedopa), BZDs, opiates, and anti-epileptic drugs (e.g., gabapentin). Sometimes the alpha-2 agonist clonidine is also used. Nonpharmacologic treatments include avoiding alcohol or nicotine use close to bedtime, massaging the affected parts of the legs, taking hot baths, applying hot or cold to the affected areas, and moderate exercise.

Other ICSD-3 Parasomnias and Sleep-Related Movement Disorders

Confusional Arousals. ICSD-3 defines Confusional Arousals as a milder form of NREM Sleep Parasomnias. It is common in young children. The child will typically partially awaken from sleep and sit up. The episodes are marked by confusion, but usually the child lies back down and resumes sleep. It is thought that confusional arousals, sleepwalking, and sleep terrors lie on a continuum.

Sleep-Related Eating Disorder. This diagnostic entity is subsumed under the DSM-5-TR classification NREM Sleep Parasomnias and specified as “sleepwalking type with sleep-related eating.” In adults, nocturnal eating can be conditioned to awakening. Eating may become obsessional, and several small meals may be eaten during the course of a night. The individual may be unaware of the activity, and weight gain can become a problem. Essentially, this syndrome’s ICSD-3 diagnostic criteria are as follows:

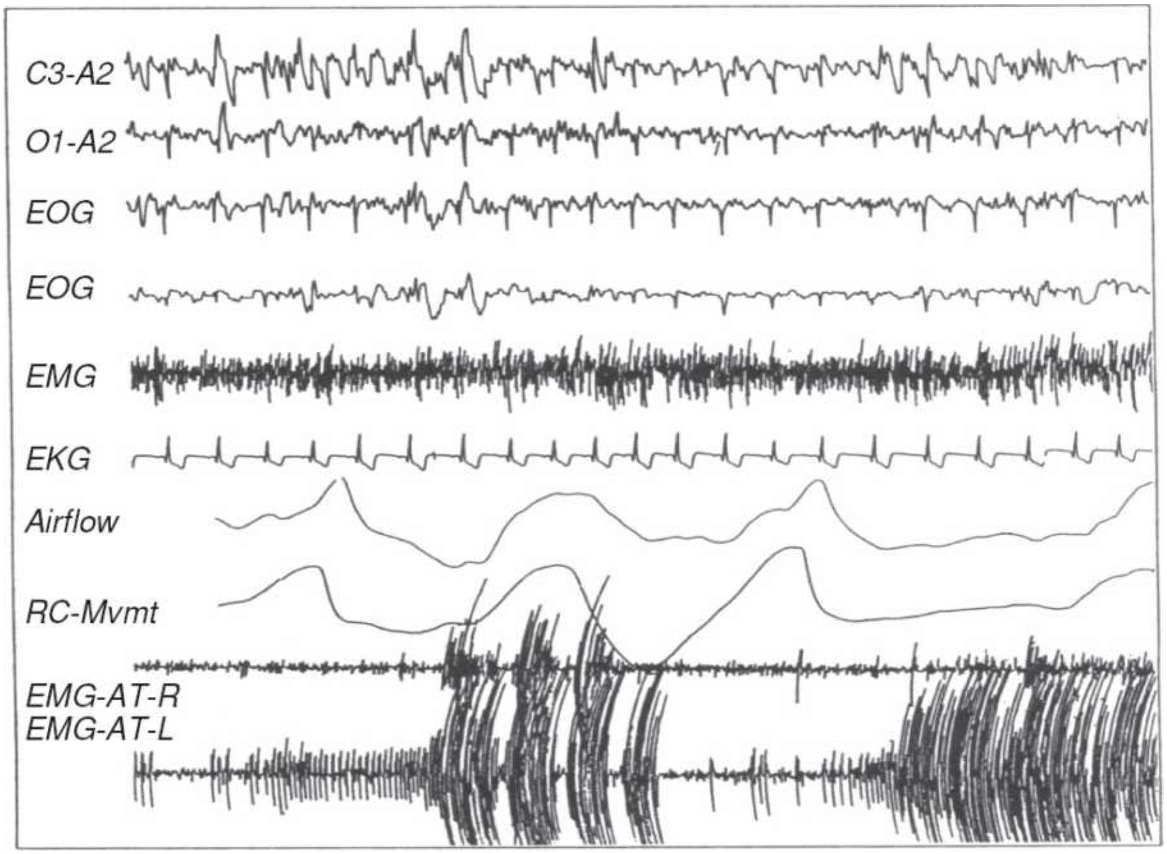

FIGURE 23–8. Restless legs syndrome. This patient presented with complaints of uncomfortable, crawling sensations in the legs when trying to fall asleep. Patients commonly report an urge to move the leg in order to dispel the sensation. This figure shows a bilateral pattern of leg EMG activity; however, the discharge is more pronounced in the left anterior tibialis (EMG-AT-L) than the right (EMG-AT-R). This pattern continued for more than an hour as the patient attempted to fall asleep; note that the sharp activity in central and occipital EEG (C3-A2 and O1-A2, respectively) and EOG is EKG artifact and not an EEG abnormality.

Table 23–5.
DSM-5 Diagnostic Criteria for Restless Legs Syndrome

A. An urge to move the legs, usually accompanied by or in response to uncomfortable and unpleasant sensations in the legs, characterized by all of the following:
   1. The urge to move the legs begins or worsens during periods of rest or inactivity.
   2. The urge to move the legs is partially or totally relieved by movement.
   3. The urge to move the legs is worse in the evening or at night than during the day, or occurs only in the evening or at night.

B. The symptoms in Criterion A occur at least three times per week and have persisted for at least 3 months.

C. The symptoms in Criterion A are accompanied by significant distress or impairment in social, occupational, educational, academic, behavioral, or other important areas of functioning.

D. The symptoms in Criterion A are not attributable to another mental disorder or medical condition (e.g., arthritis, leg edema, peripheral ischemia, leg cramps) and are not better explained by a behavioral condition (e.g., positional discomfort, habitual foot tapping).

E. The symptoms are not attributable to the physiologic effects of a drug of abuse or medication (e.g., akathisia).

Table 23–6.
International Study Group Diagnostic Criteria for Restless Legs Syndrome

Essential features	An urge to move legs, usually accomplished or caused by uncontrollable or unpleasant sensations in the legs
	The urge to mover, or unpleasant sensations that begin or worsen during periods of rest or inactivity such as lying or sitting
	The urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues
	The urge to move or unpleasant sensations are worse in evening or night than during the day or only occur in the evening or night
Common features	Positive family history: 3–5 times higher prevalence of RLS among first-degree relatives
	Response to dopaminergic therapy
	PLM during sleep or wakefulness
	Clinical course: middle-age onset and usually with progressive course
	Sleep disturbance resulting in sleep-onset insomnia or daytime sleepiness
	No abnormality in primary form of the syndrome

Reprinted from Allen RP, Picchietti DL, Garcia-Borreguero D, et al; International Restless Legs Syndrome Study Group. Restless legs syndrome/Willis-Ekbom disease diagnostic criteria: updated International Restless Legs Syndrome Study Group (IRLSSG) consensus criteria–history, rationale, description, and significance. *Sleep Med.* 2014;15(8):860–873. a. The patient has recurrent sleep-related eating episodes.
b. The patient consumes peculiar foods, food combinations, or toxic substances; creates a hazard or is injured during food preparation (e.g., starting a fire on the stove); or the patient suffers adverse health consequences from sleep-related eating (e.g., substantial weight gain).
c. The eating is associated with partial or complete amnesia and general lowering or loss of conscious awareness.

d. The eating is not better explained by another disorder, medications, or other substance use.

Recurrent Isolated Sleep Paralysis. Sleep paralysis is, as the name implies, an inability to make voluntary movements during sleep. ICSD-3 lists it as a parasomnia when it occurs at sleep onset or upon awakening, a time when the individual is partially conscious and aware of the surroundings. This inability to move can be extremely distressing, especially when coupled with the feeling that there is an intruder in the house or when hypnagogic hallucinations are occurring. Sleep paralysis is one of the tetrad of symptoms associated with narcolepsy; however, it is known to occur (with or without hypnagogia) in individuals with neither cataplexy nor excessive daytime sleepiness. Although sometimes frightening, sleep paralysis is a feature of normal REM sleep briefly intruding into wakefulness. The paralysis may last from one to several minutes. Interestingly, sleep paralysis with hypnagogia may account for a variety of experiences where the sleeper is confronted or attacked by some sort of creature. The common description is that a “presence” was felt to be near, the individual was paralyzed, the creature talks, attacks, or sits on the sleeper’s chest, and then vanishes. Whether it is called incubus, “Old Hag,” vampire, ghost oppression (kanashibari), witch riding, or alien encounter, elements common to sleep paralysis are seen. Irregular sleep, sleep deprivation, psychological stress, and shift work are thought to increase the likelihood of sleep paralysis occurring. Occasional sleep paralysis occurs in 7% to 8% of young adults. Estimates of at least one experience of sleep paralysis during the lifetime range from 25% to 50%. Improved sleep hygiene and assuring sufficient sleep are first-line therapies. Sometimes, if the individual voluntarily makes very rapid eye movements or is touched by another person, the episode will terminate.

Exploding Head Syndrome. Individuals with this parasomnia “hear” a loud imagined noise or a sense of a violent explosion in the head just as they are about to fall asleep or during a nocturnal awakening. The experience can occur just once or recurrently. There is no pain associated with the noise, but the individual may be concerned that they are having a stroke or that something is very wrong. Even a single episode can trigger severe insomnia. There are no known neurologic consequences to this syndrome.

Sleep-Related Hallucinations. Sleep-Related Hallucinations are typically visual images occurring at sleep onset (hypnagogic) or on awakening (hypnopompic) from sleep. Sometimes difficult to differentiate from dreams, they are common in patients with narcolepsy. Complex hallucinations are rare and usually happen with abrupt awakening and without remembering dreaming. Images tend to be vivid and immobile and persist for several minutes (usually disappearing when a light is turned on). The images can be frightening.

Sleep Enuresis. Sleep enuresis is a disorder in which the individual urinates during sleep while in bed. In adults, sleep enuresis often accompanies severe obstructive sleep apnea, and in such cases, it would fall into the category of parasomnia related to a medical disorder. In children, bedwetting, as it is commonly called, has primary and secondary forms. In children, primary sleep enuresis is the continuance of bedwetting since infancy. Secondary enuresis refers to relapse after toilet training was complete and there was a period where the child remained dry. Usually, after toilet training, bedwetting spontaneously resolves before age 6 years. Prevalence progressively declines from 30% at age 4 to 10% at age 6 to 5% at age 10, and 3% at age 12. Parental primary enuresis increases the likelihood that the children will also have enuresis. A single recessive gene is suspected. Secondary enuresis in children may occur with the birth of a sibling and represent a “cry for attention.” Secondary enuresis can also be associated with nocturnal seizures, sleep deprivation, and urologic anomalies. In adults, sleep enuresis is sometimes seen in patients with sleep-disordered breathing. In most cases, embarrassment, shame, and guilt are the most serious consequence. Nonetheless, if sleep enuresis is not addressed, it may leave psychosocial scars.

Treating sleep enuresis involves medication, behavioral interventions, or both. Among medications, desmopressin acetate is the preferred choice. An evidence-based medicine review of 47 randomized trials found efficacy with desmopressin. Other medications used to treat sleep enuresis include imipramine and oxybutynin chloride. Behavioral treatments, including bladder training, using conditioning devices (bell and pad), diet modification, and fluid restriction, have reportedly had good success when properly administered. Other treatments include psychotherapy, motivational strategies, and hypnotherapy.

Parasomnia Due to a Medical Disorder. Seizure disorder should always be on the top of a differential diagnoses list for most parasomnias. In fact, the AASM practice guidelines concerning the indications for polysomnography include using sleep testing to rule out seizures when diagnosing sleep terror, sleepwalking, RBD, nightmares, and other parasomnias (see Fig. 23–9). Sleep-related breathing disorders are also known to trigger sleepwalking, enuresis, sleep terror, confusional arousal, and nightmares. RBD is associated with a variety of neurologic conditions, including Parkinson disease, dementia, progressive supranuclear palsy, Shy–Drager syndrome, narcolepsy, and others.

Parasomnia Due to Drug or Substance Use. Many drugs and substances can trigger parasomnias, particularly those compounds that lighten sleep; however, alcohol is notorious for producing sleepwalking (especially in individuals who have taken sleeping pills). RBD can be provoked or worsened by biperiden, tricyclic antidepressants, monoamine oxidase inhibitors, caffeine, venlafaxine, selegiline, and serotonin agonists. RBD may also occur during withdrawal from alcohol, meprobamate, pentazocine, and nitrazepam. Medications known to provoke nightmares include L-DOPA and beta-blockers. Nightmares can also be caused by drug-induced REM sleep rebound (e.g., withdrawal from REM suppressing drugs like methamphetamine), beta-blockers, and alcohol abuse or withdrawal.

Periodic Limb Movement Disorder. Periodic Limb Movement Disorder (PLMD), previously called nocturnal myoclonus, involves brief, stereotypic, repetitive, nonepileptiform movements of the limbs, usually the legs. It occurs primarily in NREM sleep and involves an extension of the big toe. A partial flexion of the ankle, knee, and hip may also occur. These movements range from 0.5 to 5 seconds in duration and occur every 20 to 40 seconds. The leg movements are frequently associated with brief arousals from sleep and, as a result, can (but do not always) disturb sleep architecture (see Fig. 23–10). The prevalence of PLMD increases with aging and can occur in association with folate deficiency, renal disease, anemia, and the use of antidepressants. Pharmacotherapy for PLMD associated with RLS is the same as RLS. Clinical trials of pharmacotherapy for other forms of PLMD are lacking. However, BZDs, especially clonazepam, reportedly improve sleep in patients with PLMD.

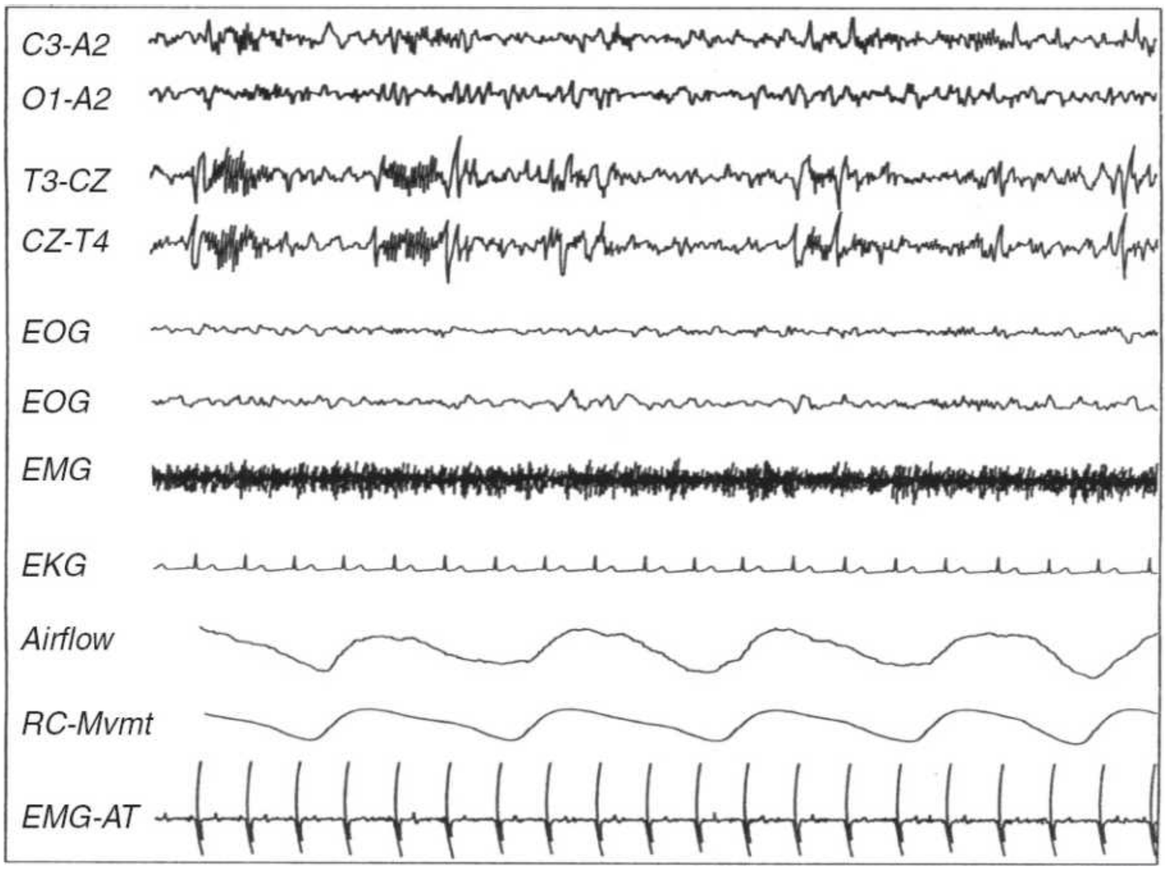

FIGURE 23–9. Polysomnographic tracing from a patient with complex partial seizures (CPS). EEG sleep spindles of excessive magnitude and duration mixed with sharp activity are visible, especially in temporal lobe derivations. The slow paper speed used in sleep studies makes it difficult to classify this activity precisely; however, the abnormality is apparent. Such a finding should be confirmed with standard clinical EEG techniques both during wakefulness and sleep.

Sleep-Related Leg Cramps. Nocturnal leg cramps are much like leg cramps that occur during wakefulness. They usually affect the calf and are painful muscle contractions. The pain awakens the sleeper and thereby disrupts sleep. Metabolic disorders, mineral deficiencies, electrolytic imbalances, diabetes, and pregnancy are known precipitators. The reason that some individuals have repeated leg cramps during sleep and not during the day is not known.

Sleep-Related Bruxism. Sleep-Related Bruxism is diagnosed when an individual grinds or clenches their teeth during sleep (see Fig. 23–11). ICSD formerly classified sleep bruxism as a parasomnia but now lists it as a sleep-related movement disorder. Sleep bruxism can produce abnormal wear on the teeth, damage teeth, provoke tooth and jaw pain, and/or make loud, unpleasant sounds that disturb the bed-partner. Sometimes atypical facial pain and headache also result. More than 85% of the population may brux at one time or another; however, it is clinically significant in only about 5%. Teeth grinding occurs in any sleep stage but appears most common at the transition to sleep, in stage 2 sleep, and during REM sleep. Some evidence indicates that teeth-grinding during REM sleep is more commonly associated with dental wear or damage. Sleep bruxism does not appear to be exacerbated by dental malocclusion but rather worsens during periods of stress. Researchers studying sleep bruxism find that many patients have less frequent teeth-grinding when sleeping in the laboratory; therefore, repeated studies may be needed to document the disorder. By contrast, bruxism frequently appears on polysomnographic recordings made for other purposes and may occur secondary to (a) sleep-related breathing disorders, (b) the use of psychostimulants (e.g., amphetamine, cocaine), (c) alcohol ingestion, and (d) treatment with some serotonin reuptake inhibitors. Differential diagnosis should rule out nocturnal seizures. Sleep bruxism can occur infrequently (monthly), regularly (weekly), or frequently (nightly). Severity is judged on the basis of sleep disruption, consequent pain, and dental damage. The usual treatment involves having the patient wear an oral appliance to protect the teeth during sleep. There are two basic types of appliances used. The soft one (mouth guard) is typically used in the short term, whereas the hard acrylic one (bite splint) is used longer term and requires regular follow-up. Relaxation, biofeedback, hypnosis, physical therapy, and stress management are also used to treat sleep bruxism. A variety of drug therapies have been tried (BZDs, muscle relaxants, dopaminergic agonists, and propranolol); however, reliable outcome data are not available.

Sleep-Related Rhythmic Movement Disorder. This sleep disorder is marked by repetitive, rhythmic movements usually involving the head and neck. Usually occurring during the transition from wakefulness to sleep, this movement disorder may also continue during light sleep. ICSD formerly classified this nosologic entity as a parasomnia, but it is now listed as a sleep-related movement disorder. The Sleep-Related Rhythmic Movement Disorder has been called by many names, including *jactatio capitis nocturna*, head banging, head rolling, body rocking, and *rhythmie* *du sommeil*. A majority of infants will body rock. Some clinicians think body rocking develops from the soothing effect of vestibular stimulation. If the rhythmic movement persists into childhood and involves head banging, the risk of injury increases. Male to female ratio is 4:1. Severity ranges from less than one episode weekly to nightly episodes producing injury.

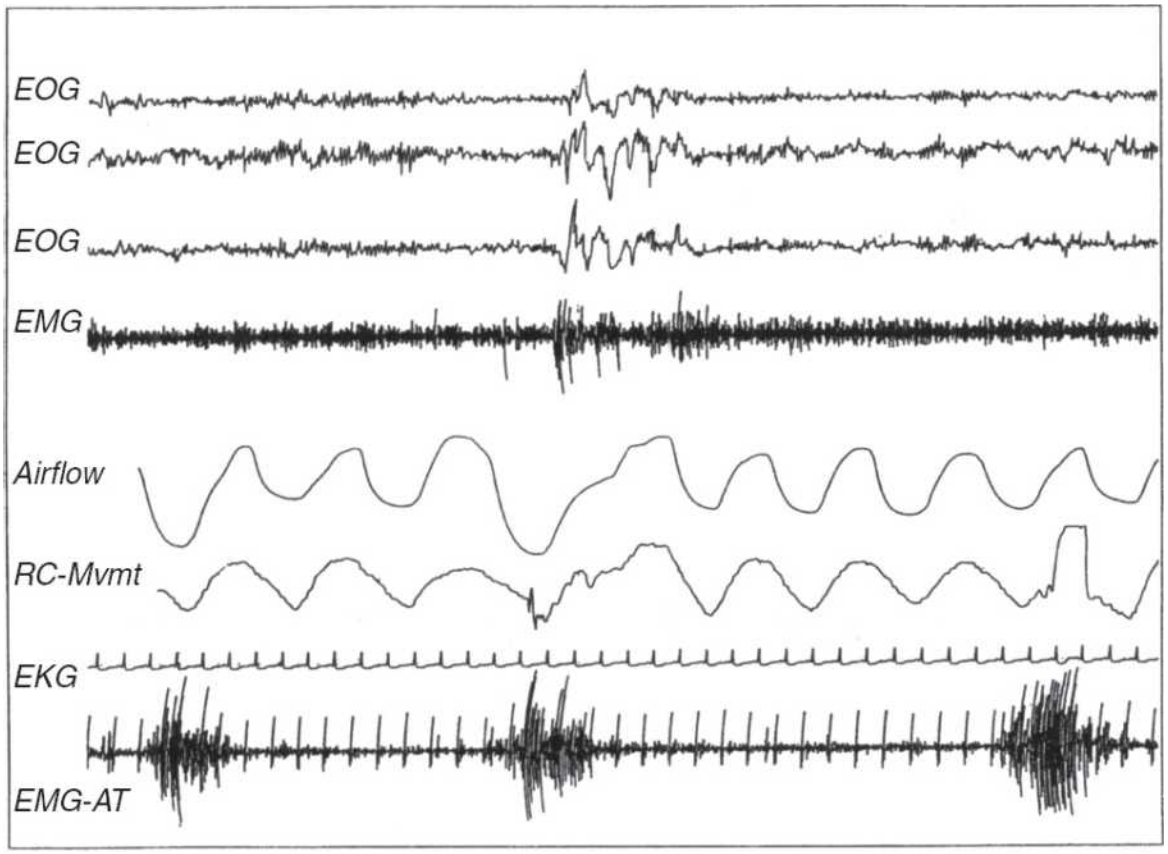

FIGURE 23–10. Polysomnographic tracing illustrating periodic leg movements in sleep. This figure shows periodic leg movements during sleep. Approximately 33 seconds of recording shown here clearly reveal a pattern of electromyographic activity in anterior tibialis (EMG-AT). The activity pattern repeats at regular intervals and sometimes produces transient arousals (note EEG-EOG-EMG) after movement at the center of the figure. This patient, whose chief complaint was nonrefreshing sleep with sleep maintenance insomnia, had more than 250 such leg movements during each night he slept in the laboratory.

Benign Sleep Myoclonus of Infancy. Previously called benign neonatal sleep myoclonus, this disorder is characterized by asynchronous jerking of limbs and trunk during quiet sleep in neonates. This benign, apparently rare parasomnia usually begins within the first week of life and may last a few days or several months. No treatment is recommended.

Propriospinal Myoclonus at Sleep Onset. This is a spinal cord mediated movement disorder, sometimes associated with spinal cord lesions. Movements appear during times of wakeful relaxation, and they may interfere with sleep onset. They start in the abdominal and truncal muscles and then progress to the neck and proximal muscles of the limbs. Treatment with clonazepam or anticonvulsants may be effective.

Sleep-Related Movement Disorder Due to a Medical Disorder. Neurologic diseases associated with daytime movement disorders can likewise be associated with sleep-related movement disorders. Stress, anxiety, and sleep deprivation may contribute to bruxism.

Sleep-Related Movement Disorder Due to Medication or Substance. A variety of medications and substances can produce or exacerbate sleep-related movement disorders. Stimulants can produce rhythmic movement disorders and bruxism. Antidepressants (including most tricyclics and selective serotonin reuptake inhibitors), antiemetics, lithium, calcium channel blockers, antihistamines, and neuroleptics can provoke Restless Legs symptoms and Periodic Limb Movement Disorder.

Sleep-Related Movement Disorder, Unspecified. ICSD-3 provides this nosologic classification for coding other unusual behaviors and otherwise unexplained movement disorders occurring during sleep.

Isolated Symptoms and Normal Variants

Sleep Talking. As the name implies, sleep talking in classic form involves unconscious speech during sleep. It is seldom recognized in an individual unless it annoys the bed partner. It can be induced by fever, stress, or conversing with the sleeper. Somniloquy may accompany sleep terror, sleepwalking, confusional arousals, OSA, and REM sleep behavior disorder.

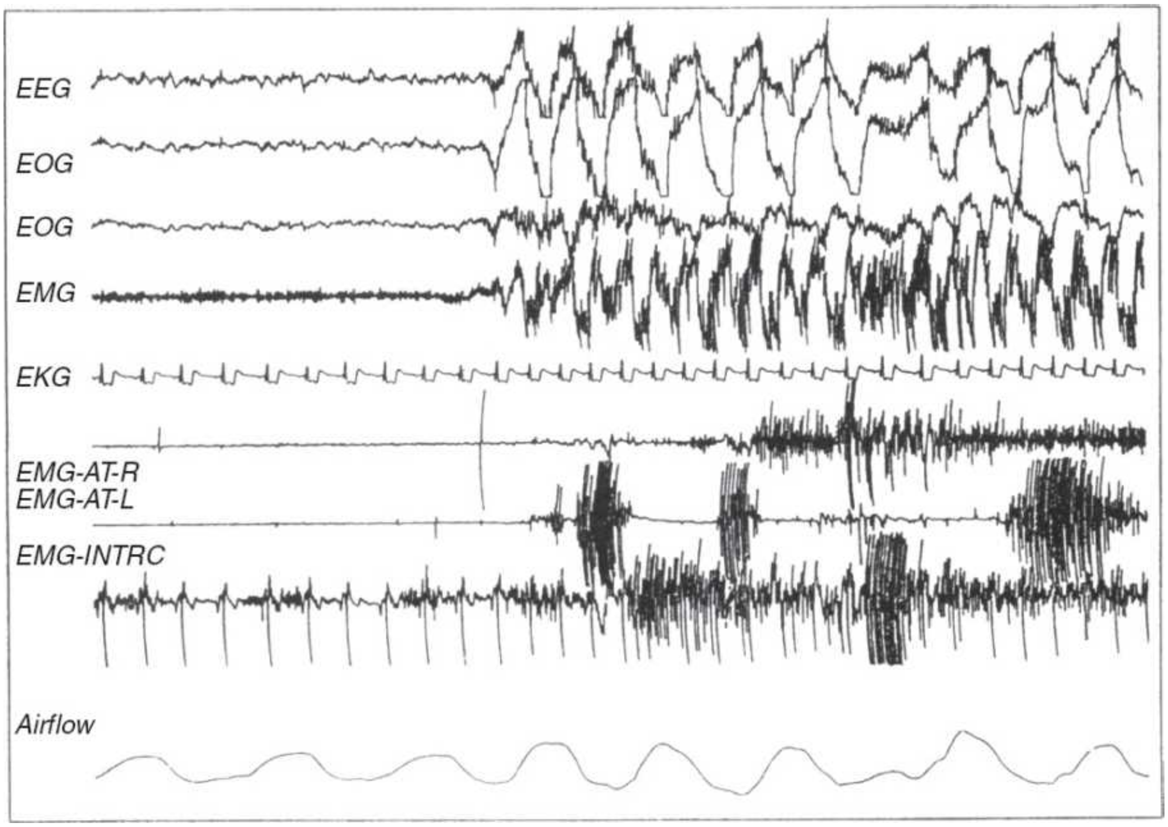

FIGURE 23–11. Polysomnographic tracing showing sleep-related bruxism. This figure showing approximately 25 seconds of tracing was obtained from a patient during an episode of bruxism. Bruxism can occur during any stage of sleep or wakefulness. The interference pattern of EEG-EOG-EMG channels is typical and reflects the rhythmic jaw movement and grinding of the teeth. This patient had many such episodes, some that caused awakening. Readily observable tooth damage and jaw pain were noted.

Excessive Fragmentary Myoclonus. These small movements or muscle fasciculations of the fingers, toes, or corners of the mouth are involuntary and can occur during wakefulness or sleep. Although little or no visible movement is present, the patient is typically aware of the twitching. In patients with apneas, twitching may worsen during periods of hypoxemia.

Hypnagogic Foot Tremor and Alternating Leg Muscle Activation. Hypnagogic foot tremor occurs at sleep onset or during stages 1 and 2 of sleep. It consists of a rhythmic movement of the toes or feet for seconds to minutes. Alternating Leg Muscle Activation consists of brief activation of the anterior tibialis in one leg and then the other.

Sleep Starts (Hypnic Jerks). Sleep starts are sudden, brief muscle contractions that occur during the transition between wakefulness and sleep in 60% to 70% of adults. The contractions commonly involve the legs; however, there is sometimes movement in the arms and head. This "hypnic jerk," as it is sometimes called, is usually benign. The sleep start, however, can interfere with the ability to fall asleep and may be accompanied by sensations of falling, a hallucinated flash of light, or a loud crackling sound. In severe cases, the sleep start produces profound sleep-onset insomnia.

SUBSTANCE/MEDICATION-INDUCED SLEEP DISORDER

Medications and substances associated with or thought to provoke sleep disorders are discussed in sections: Insomnia Due to Drug or Substance; Characteristics and Hypersomnolence Disorder Subtypes; Central Sleep Apnea Due to Medication or Substance; Parasomnia Due to Drug or Substance; and Sleep Related Movement Disorders Due to Medication or Substance.

TOOLS IN SLEEP MEDICINE

Clinical Interview

A careful and thorough clinical interview remains one of the most informative parts of a patient workup for sleep disorders. The habitual bedtime and arising times for both weekdays and weekends, the frequency, duration, and how refreshing naps are, and overall levels of sleepiness and satisfaction with sleep are good places to begin. Specific sleep problems relating to difficulty initiating and maintaining sleep are important, including whether there is rumination at bedtime, fear of not being able to sleep, or excessive worry when attempting to sleep. Leg movements, leg sensations, leg cramps, teeth grinding, dream enactments (with or without injury), and other movements should be queried. Morning headaches, morning dry mouth, nocturnal reflux, hyperhidrosis, nocturia, enuresis, nocturnal tongue biting, nightmares, sleep terrors, and other sleep-related problems should be reviewed. The presence of family pets and whether they sleep in the bedroom (or bed) can be important in some cases.

Polysomnography

Polysomnography is the continuous, attended, comprehensive recording of physiologic activity during sleep. A polysomnogram is typically recorded at night and is 6 to 8 hours in duration. Brain wave activity, eye movements, submentalis electromyography activity, nasal-oral airflow, nasal pressure, respiratory effort, oxyhemoglobin saturation, heart rhythm, and leg movements during sleep are recorded. Body position is usually noted, and snoring sounds may be recorded. Brain wave activity, eye movements, and submentalis electromyogram are important for identifying sleep stages and central nervous system arousals. Muscle tension and movements subside with deeper sleep and can also be useful in diagnosing periodic limb movement disorder and RLS. Nasal airflow, nasal pressure, respiratory effort, and oxyhemoglobin saturation are instrumental in diagnosing sleep apnea and other sleep-related breathing disorders.

Indications for polysomnography include:

1. diagnosis of sleep-related breathing disorders
2. PAP titration and assessment of treatment efficacy
3. evaluation of sleep-related behaviors that are violent or may potentially harm the patient or bed partner
4. differentiating narcolepsy from other hypersomnolence disorders
5. differentiating parasomnias from nocturnal seizures.

Polysomnography can also be used to diagnose atypical parasomnias, sleep-related problems secondary to neuromuscular disorders, periodic limb movement disorder, and arousals secondary to a seizure disorder. Also, patients with excessive daytime sleepiness, or those who wake up gasping or choking, should be referred for polysomnography. A sleep study is not needed to diagnose restless leg syndrome.

Polysomnography is also recommended to assess sleep quality and quantity on the night prior to a Multiple Sleep Latency Test (MSLT) being conducted to diagnose narcolepsy.

Home Sleep Apnea Testing (HSAT)

HSAT involves recording a limited number of cardiopulmonary parameters to assess patients for sleep-related breathing disorders. HSAT may include limited channels of EEG recording for sleep staging. HSAT is much less expensive than polysomnography. Usually, airflow, respiratory effort, heart rhythm, snoring sounds, and oximetry are recorded. HSAT devices will detect sleep apnea in patients with moderate-to-severe pathophysiology. Negative studies are problematic because HSAT is less sensitive than full laboratory polysomnography. Patients with negative tests should be scheduled for laboratory polysomnography, notwithstanding obvious symptoms or comorbidity. Additionally, HSAT does not check for the full spectrum of sleep disorders; therefore, after a breathing disorder is diagnosed and treated, residual symptoms need careful follow-up.

Multiple Sleep Latency Test

The MSLT is indicated for diagnosing narcolepsy. Every 2 hours, beginning 2 hours after morning awakening, a 20-minute nap opportunity is provided. The patient is instructed to let themself fall asleep; that is, to not resist falling asleep. Electroencephalographic, electrooculographic, and submentalis electromyography activity are recorded to determine sleep stage. The latency to sleep is used to assess hypersomnolence, and the appearance of REM sleep on two or more nap opportunities confirms narcolepsy (or on one nap if the previous night's polysomnography revealed REM sleep within 15 minutes of sleep onset). If the patient falls asleep on a given nap opportunity, the nap is terminated 15 minutes after initial sleep onset. If the patient does not fall asleep, the session is terminated after 20 minutes of recording. A total of five nap opportunities are provided at 2-hour intervals across the day.

Maintenance of Wakefulness Test

Similar procedurally to MSLT, the maintenance of wakefulness test (MWT) provides 40-minute test sessions at 2-hour intervals across the day. However, the patient is instructed to try and remain awake and resist sleep rather than not resist sleep. This technique is used to assess treatment outcomes and is sometimes required as part of “fit for duty” testing. Patients sit in a comfortable chair or on the bed with a bolster pillow in a darkened room while recordings are made. The first epoch of stages 2, 3, 4, or REM or three consecutive epochs of stage 1 mark unequivocal sleep onset. Falling asleep on MWT indicates some level of sleepiness. 59% of volunteers (presumably normal) remain awake for the entire 40 minutes across all four trials (using unequivocal sleep criteria). Any sleep latency <8 minutes is abnormal. Sleep latency ranging from 8 to 40 minutes is of unknown significance. The mean sleep latency (first sleep epoch) is 30.4 ± 11.2 minutes, and the upper 95% confidence interval is 40 minutes.

Actigraphy and Sleep Diary

An actigraph is a device that measures and records movement. It is usually worn on the wrist (like a watch) and can be used to measure the sleep–wake cycle. Depending on the model and the settings, it can make continuous recordings for days or weeks. It can be especially useful for assessing insomnia, circadian rhythm disorders, movement disorders, or an assortment of rare events. Research grade actigraph recorders are validated test instruments. Recently, the public's increased awareness and focus on fitness has spawned a market for consumer electronic devices that are essentially actigraphic recording devices. Many of these products purport to measure sleep and wakefulness; however, the precision and accuracy levels are unknown. A sleep diary can be used alone or with actigraphy to better identify the sleep–wake cycles of individuals with insomnia or circadian rhythm sleep–wake disorders. A sleep diary can be completed daily for a week or more, showing the bed and rise times, sleep-onset latency, wake after sleep onset, and sleep duration. It can also show the intake of CNS acting agents, including medications, caffeine, and alcohol intake in relation to the sleep–wake cycle.

Subjective Tools

STOPBANG. ***S***noring, ***T***iredness, ***O***bserved apnea, high blood ***P***ressure, ***B***MI, ***A***ge, ***N***eck circumference, and male ***G***ender is an eight-item yes/no sleep apnea risk screening tool with a minimum of zero and a maximum of 8, with the higher number indicating a higher risk of sleep apnea. The tool was initially developed to screen patients who undergo general anesthesia. However, it has gained widespread use as a sensitive screening tool for sleep apnea since then.

Epworth Sleepiness Scale (ESS). ESS is an eight-item subjective tool that asks the respondent to rate the probability of falling asleep in eight different circumstances, even if the responder has not been in that situation. Each condition will be scored from zero to three, with the total score from zero to 24. A higher score indicates higher sleepiness. Scores of 12 and above are considered abnormal. ESS is a measure of subjective sleepiness in contrast to MSLT, which measures physiologic sleepiness.

Insomnia Severity Index. The ISI is a seven-item subjective tool that measures a patient's perception of their insomnia. It not only measures the insomnia-related symptoms but also the effects of insomnia and how much the individual is concerned or distressed because of insomnia. Each item can be scored from 0 to 4 with maximum of 28. An ISI of 10 or higher identifies insomnia with high sensitivity and specificity. ISS is mostly used in research, but it can be easily used in a sleep practice.

SLEEP DISORDERS CASES

CASE STUDY 1 (HYPERSOMNIA)

DESCRIPTION

Mr. J is a 28-year-old single male with an approximately 10-year history of fatigue and sleepiness in the daytime. He began to recognize daytime sleepiness as a problem in his first year of college when he would fall asleep in class or the dormitory. He admits that his sleep–wake schedule was disrupted during college due to taking long naps and then staying up until 1:00 or 2:00 A.M. to complete his studies. His grades and social life suffered, and he describes himself as depressed, isolated, and hopeless about his planned future as a certified public accountant (CPA).

As a child, Mr. J. says he slept "normally." In high school, he felt best with 10 hours of sleep per night and functioned well in the daytime. Mr. J denies abuse of alcohol or drugs. He does not use tobacco and drinks about 8 to 10 cups of coffee per day. Family history is negative for known sleep or psychiatric disorders. Physical examination findings are noncontributory except for a body mass index of 0.29. Routine labs are normal, including TSH.

Mr. J's excessive sleepiness has continued to the present day, notwithstanding some improved sleep hygiene. Improvements include a more consistent bedtime, trying not to nap, and a torturous month-long trial without caffeine. He remains dysphoric and discouraged about his future, blaming his chronic sleepiness as the continuing impediment to his life plans. "I'm just tired of being tired," he says.

Currently, his bedtime is between 10:00 and 10:30 P.M.; his wake-up alarm is set for 6:30 A.M. He oversleeps at least once a week on workdays and sleeps from 10:30 P.M. until 10:00 A.M. on weekends in an attempt to "catch up." He has difficulty awakening and feels unrefreshed or mildly refreshed. By drinking six to eight cups of coffee in the morning, he can usually avoid dozing during the morning. Luckily, he is an independent CPA and can schedule client appointments during this relatively alert time. After lunch, he routinely falls asleep at the computer while working. He sleeps for 20 to 60 minutes and is usually awakened by his secretary. He then drinks another two cups of coffee and continues with his work. Unexpected napping can also occur later in the afternoon or evening, and he has "nodded off" while driving. He sleeps alone; however, he has been told that he snores loudly. He does not awaken gasping or choking. He denies hypnagogic hallucinations and sleep paralysis but thinks he may feel weak after the rare occasions when he participates in a heated argument.

DISCUSSION OF CASE 1

Mr. J has one of the hypersomnias. His history is most consistent with obstructive sleep apnea syndrome, idiopathic hypersomnia, sleep deprivation in a long sleeper, dyssomnia associated with mood disorder, and narcolepsy. The ancillary symptoms of narcolepsy are absent, with the possible exception of cataplexy. When cataplexy occurs clearly, the diagnosis of narcolepsy is strongly indicated. However, Mr. J's possible infrequent weakness during heated arguments is equivocal for cataplexy. His persistent desire for a 10-hour sleep period would be unusual for a patient with narcolepsy.

A long sleeper or an individual with idiopathic hypersomnia requires prolonged sleep periods and may awaken groggy, as does Mr. J. The main differentiating feature is that whenever consistently given a chance to have a full nightly sleep period (usually 10 to 12 hours), the long sleeper does not experience excessive daytime sleepiness. Furthermore, there may be associated autonomic nervous system dysfunction or polysomnographic evidence of elevated slow wave sleep percentage in patients with idiopathic hypersomnia.

Sleepiness associated with a low-grade chronic depression may be difficult to differentiate from other causes of hypersomnolence. Polysomnography, psychiatric interview, and psychometric testing can be helpful. Mr. J relates his dysphoria to sleepiness and not vice versa; nonetheless, a dyssomnia associated with mood disorder should be considered.

Obstructive sleep apnea syndrome is a strong possibility. Mr. J is overweight (BMI = 0.29) and snores loudly. Many patients are unaware of gasping or choking for breath. Often, family members witness cessation of breathing during sleep and urge patients to seek treatment. However, Mr. J lives and sleeps alone.

Polysomnography is recommended in patients suspected of obstructive sleep apnea syndrome, narcolepsy, or idiopathic hypersomnia. These disorders usually require lifelong treatment and have significant morbidity and mortality if untreated.

CASE STUDY 2 (PARASOMNIA)

DESCRIPTION

Ms. R is a 20-year-old woman who was referred with symptoms of talking, mumbling, and crying out during sleep. At least twice per week, she screams in her sleep. She is bothered with excessive sleepiness and falling asleep inappropriately, such as during a conversation. When inactive, she is tired and sleepy, even after a full 8-hour night of sleep. However, she has energy when motivated and leads a vigorous life. Once, she awakened outside of her apartment, and her roommate had to let her back in because she had locked herself out. She does not recall the sleepwalking episode or other nocturnal wanderings but sometimes remembers yelling. From the history, crying seems to occur in light sleep, but she rarely recalls any sleep-related thoughts or dreams. However, there is a history of occasional nightmares and bruxism. The patient uses an oral appliance to protect her teeth. Leg-kicking and mild snoring without gasping or choking are noted. The patient also complains of leg-kicking during sleep. Her sleep–wake schedule is irregular, and she averages between five and seven hours of sleep per night. She occasionally awakens with a headache in the morning.

Previous health history includes a hospitalization for febrile convulsions during infancy, ophthalmologic surgery for strabismus during childhood, and tonsillectomy as a teenager. Health is otherwise excellent. The patient does not smoke tobacco or drink alcohol.

DISCUSSION OF CASE 2

By history, Ms. R has one or more of the parasomnias. Sleep talking alone does not require a sleep study, but this patient has nocturnal wanderings. Polysomnography with clinical EEG is indicated to rule out unrecognized nocturnal seizure disorder or other organic factors inducing sleepwalking. Sleepwalking is common and not necessarily abnormal in young children; however, it is rare in adults and merits careful evaluation. Ms. R’s excessive daytime sleepiness is likely due to insufficient sleep (5 to 7 hours per night) and possibly parasomnia-related disruption. Interestingly, many parasomnias are exacerbated by sleep deprivation, as is nocturnal seizure disorder.

Sleep studies were performed using comprehensive, attended, laboratory polysomnography. Prior to the overnight study, a clinical EEG was performed. The clinical EEG study did not reveal any significant abnormal EEG activity during baseline, photic stimulation, or hyperventilation. An extended EEG montage was used during the sleep study. Overall sleep quality was within the normal range. Sleep efficiency was 96%, and latency to sleep was 1 minute. REM sleep percentage was elevated (31%), and latency to REM sleep was less than normal (57 minutes). Slow wave sleep was normal in percentage, but EEG delta activity was very high amplitude. The overall macroarchitectural sleep pattern suggested rebound from sleep deprivation.

By contrast, sleep microarchitecture contained many abnormal features. We observed high-amplitude paroxysmal EEG bursts. Excessively prolonged sleep spindles were noted, and rhythmic K complexes were observed (see Fig. 23–12). There was one arousal out of slow wave sleep with rhythmic EEG discharges alternating with sharp waves. Sharps and spikes occurred several times; however, the focus was difficult to localize (possibly right temporal lobe). There were frequent body movements and full body jerks, most of which occurred during NREM sleep. There were episodes of moaning during slow wave sleep and laughing during stage 2 sleep, followed by high-amplitude theta bursts and REM sleep. We observed frequent movements and arousals from REM sleep but no REM-related spikes or sharp waves. Seizure-like EEG activity was noted during the night and occurred predominantly during slow wave sleep. However, the patient did not attempt to sleepwalk. Sharp wave and spike activity increased during the final 45 minutes of the sleep study.

The patient did not have sleep-related breathing impairment, and SaO_2 nadir was 90%. She had no periodic limb movements during sleep, and polygraphic features associated with restless legs syndrome were absent.

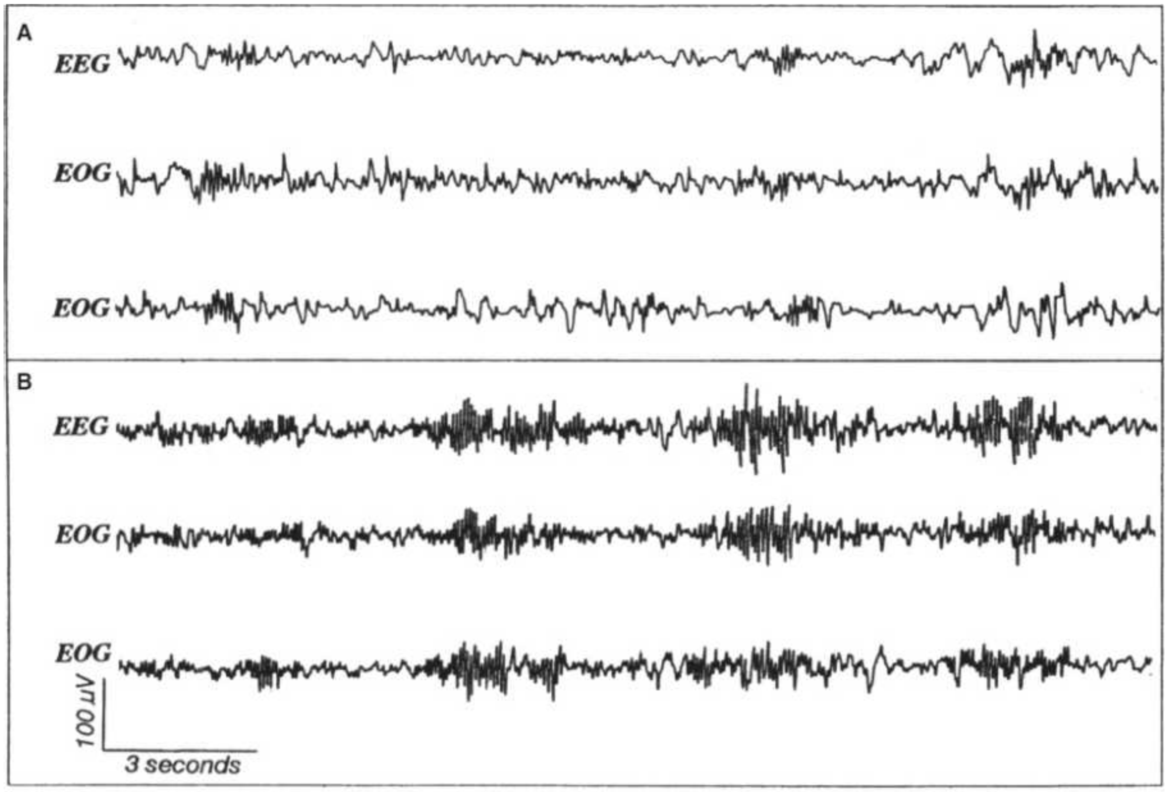

FIGURE 23–12. Polysomnographic tracings illustrating normal and excessive spindle activity. Polysomnographic tracings comparing normal sleep spindle EEG activity during stage 2 sleep (**Panel A**) with that of a patient chronically using a benzodiazepine (**Panel B**). This patient, who had been treated with benzodiazepines for more than a decade (and currently taking an extremely high dose) before being seen at the sleep disorders center. Sleep was grossly abnormal. The most obvious aberration was the tremendous increase in the frequency, magnitude, and duration of EEG spindle activity (see **Panel B**). Additionally, slow-wave sleep was absent, stage 2 was grossly elevated, and spindles even intruded into REM sleep.

CASE STUDY 3 (INSOMNIA)

DESCRIPTION

Ms. W is a 41-year-old female presenting with a two and one half year complaint of sleeplessness. She has difficulty falling asleep (30 to 45 minutes sleep onset latency) and awakens every hour or 2 after sleep onset. These awakenings may last 15 minutes to several hours, and she estimates approximately 4.5 hours of sleep on an average night. She rarely takes daytime naps, notwithstanding feeling tired and edgy. The patient describes her sleep problem with the following words: “It seems like I never get into a deep sleep. I have never been a heavy sleeper, but now the slightest noise wakes me up. Sometimes I have a hard time getting my mind to shut down.” She views the bedroom as an unpleasant place of sleeplessness and states, “I tried staying at a friend’s house where it is quiet, but then I couldn’t sleep because of the silence.”

At times, Ms. W is unsure whether she is asleep or awake. She has a history of clock-watching (to time her wakefulness) but stopped doing this when she realized it was contributing to the problem. The insomnia is unrelated to seasonal changes, menstrual cycle, or time-zone translocation. Her basic sleep hygiene is good. Appetite and libido are unchanged. She denies mood disturbance, except that she is quite frustrated and concerned about sleeplessness and its effect on her work. Her work involves sitting at a microscope for six of a nine-hour working day and meticulously documenting her findings. Her final output hasn’t suffered, but she must now “double-check” for accuracy.

She describes herself as a worrier and a Type-A personality. The patient does not know how to relax. For example, on vacation, she continually worries about things that could go wrong. She will not even begin to unwind until she has arrived at the destination, checked in, and unpacked. Even then, she is unable to relax.

Medical history is unremarkable except for tonsillectomy (age 16 years), migraine headaches (current), and diet-controlled hypercholesterolemia. She takes naproxen as needed for headaches. She does not currently drink caffeinated beverages, smoke tobacco, or drink alcoholic beverages. She does not use recreational drugs.

The problem with insomnia began after relocation to a new city and place of employment. She attributes her insomnia to the noisy neighborhood in which she now lives. She first sought treatment 18 months ago. Her family practice physician diagnosed depression, and she was started on fluoxetine, which made her “climb the walls.” Antihistamines were tried next with similar results. She was then switched to low-dose trazodone (for sleep) and developed nausea. After these medical interventions, she sought medical care elsewhere. Zolpidem 5 mg was prescribed, but it made her feel drugged, and upon discontinuation, she had withdrawal effects. Another family practice physician diagnosed “nonspecific anxiety disorder” and began buspirone, an experience she describes as “having an alien try to climb out of my skin.” Buspirone was discontinued. Paroxetine was tried for 8 weeks with no effect. Finally, a psychiatrist was consulted, who diagnosed adult attention deficit disorder (without hyperactivity) and suggested treatment with methylphenidate. At this point, the patient was convinced that a stimulant would not help her insomnia and demanded a referral to a sleep disorders center.

DISCUSSION OF CASE 3

Ms. W’s symptoms fall into the broad category of insomnia, and the symptoms began after moving from one city to another. Environmental sleep disorder (noise) and adjustment sleep disorder (new job, city, and apartment) are likely initial diagnoses. However, a more chronic, endogenous problem has become operative. What is it? Ms. W is a “worrier” and meticulous but doesn’t reach diagnostic criteria for personality or anxiety disorders. Dyssomnia associated with mood disorder should be considered in any patient with sleep maintenance problems and early morning awakening insomnia. However, this patient does not have other significant signs of depression. Unfortunately, many patients are misdiagnosed with depression or “masked depression” on the sole basis of an insomnia complaint and unsuccessfully treated with antidepressant medication. Ms. W’s job demands long hours with focused concentration. Her job performance has been superior for many years, notwithstanding insomnia. Thus, a diagnosis of attention deficit disorder is unlikely. Idiopathic insomnia implies a childhood complaint, which Ms. W denies.

The likely working diagnosis is psychophysiological insomnia (PPI). There may be some sleep state misperception (sometimes unclear of whether she is awake or asleep), but this cannot adequately account for the constellation of symptoms. An initial treatment plan should include further documentation of the sleep pattern using a sleep log. Behavioral treatments will likely benefit this patient. Medications with sedative effects are sometimes useful during the initial treatment of PPI. However, thus far, they have done more harm than good in this patient. She is likely to be a challenging patient to treat.

CASE STUDY 4 (PTSD AND INSOMNIA)

DESCRIPTION

Mr. M., age 68, is a retired army officer who with a history of combat. He was referred to the sleep disorders center to evaluate chronic complaints of insomnia. Mr. M was in active service on the battlefield for 8 years and suffered what some describe as “blast-wave” or “shell shock,” leading to PTSD from frequent exposure to explosions. After a full evaluation in the psychiatry ward, he was diagnosed as suffering from chronic war–induced PTSD.

Following his retirement from the military, Mr. M was unable to work due to mental illness. Twenty-five years following his wartime experiences, he still complained of disabling insomnia that was resistant to treatment. He described the insomnia as “an umbrella that covers all of his other symptoms,” which included severe aggression and poor relationships with his family, including his wife. He said that he had a good day after a good night’s sleep and that after suffering a bad night, he experienced severe symptoms. He begged the psychiatrist to help him to get better sleep, and he emphasized, “I cannot sleep a wink.” He feels guilty following frequent outbursts of verbal aggression toward his wife. He also feels isolated due to the insomnia and does not participate in any social or leisure activities. Both his wife and his referring physician feel that Mr. M. is malingering; in fact, his wife states that he sleeps well and even upsets her sleep due to his snoring.

A psychiatric evaluation in our clinic yielded a score of 10 on the Pittsburgh Sleep Quality Index (PSQI), which implies poor sleep quality. Two consecutive nights of assessment by polysomnography yielded normal sleep patterns. After excluding significant secondary gain, he was diagnosed with paradoxical insomnia and treated with nonpharmacologic treatment, mainly Cognitive Behavior Therapy for insomnia (CBTi). The therapy was relatively successful: following 8 weeks of therapy, his PSQI score decreased to 6, and he reported subjective satisfaction and improvement in his sleep.

DISCUSSION OF CASE 4

Difficulty falling or staying asleep and nightmares are symptoms included in the DSM-5-TR diagnostic criteria for PTSD. Patients with chronic war-induced PTSD with insomnia complaints often have an insomnia disorder. Similarly, Mr. M. had both chronic war-induced PTSD and comorbid chronic insomnia disorder. This case highlights four points. First, subjective complaints about insomnia should not be ignored, as they reveal the unique personal experience and perspective of a given patient even if they mismatch with objective data. Some might even consider overlooking of subjective perspectives as maltreatment; at least, inaccurate labels of malingering can invoke great distress for patients. Second, when there is a discrepancy between subjective and objective measurements of sleep, with subjective measures indicating greater sleep problems than objective measures, psychotherapeutic interventions such as CBT can be effective. We found that to be the case with Mr. M. Third, careful gathering of subjective sleep complaints is critical. Sometimes patients will express concern about particular aspects of their sleep health, and treatment of those subjective complaints through CBT can improve sleep. We found this also with Mr. M. Fourth, objective measurements should not be ignored. They can be valuable to complete diagnostic processes, evaluate progress, and exclude other sleep disorders such as sleep-related breathing disorders.

In conclusion, subjective and objective measurements are two faces of “the sleep assessment coin” in patients with PTSD. Each perspective has unique value in diagnosing and treating patients.

SUMMARY

Sleep medicine is an important, rapidly evolving discipline. There is great diversity in presenting complaints, etiology, course, and treatment of sleep disorders. Several nosologic systems exist for classifying sleep disorders; however, the ICSD-3 appears to be the most comprehensive. Sleep disorders significantly alter an individual’s health, mood, quality of life, and cognitive ability. Sleep disorders may be primary; however, many are associated with other medical, neurologic, and psychiatric conditions. Disturbances in sleep or wakefulness may also result from substance use or abuse. Sleep disorders are particularly important for psychiatrists because insomnia and hypersomnia commonly occur in a wide range of psychiatric conditions. With appropriate treatment, most sleep disorders can be effectively managed. The extent of improvement in a patient’s general well-being after treatment is usually dramatic. A good night of sleep is as important to general health as nutrition and exercise.

Impulse-Control Disorders

24.1 Intermittent Explosive Disorder

Taylor A. Ochalek, Ph.D., and F. Gerard Moeller, M.D.

DIAGNOSIS AND EPIDEMIOLOGY

Intermittent explosive disorder (IED) in DSM-5 and its text revision (DSM-5-TR) represents a disorder of recurrent, problematic, reactive (i.e., affective or impulsive), aggressive behavior that, over the lifetime, affects about 5% to 8% of individuals in the United States. Key diagnostic features of IED of DSM-5-TR include: (1) aggressive outbursts have a rapid onset, typically without any premeditation, last for less than 30 minutes, and usually occur in response to provocation by a known individual; (2) less severe episodes (verbal or noninjurious physical) often intersperse between more severe episodes; (3) the disproportionate impulsive-aggressive response to a psychosocial stressor; (4) aggressive outbursts are impulsive or provoked by anger and cause significant distress or impairment in psychosocial functioning; (5) the individual is above the age of 6 years or comparable developmental level; (6) the aggressive acts are “not better accounted for” by other DSM-5 disorders or drugs or a documented general medical condition (see Table 24.1–1). As described in DSM-5-TR, differential diagnosis section, a diagnosis of IED should not be given to individuals if the aggressive symptoms are better explained by another disorder such as disruptive mood regulation disorder, antisocial personality disorder (ASPD), or borderline personality disorder, delirium, major neurocognitive disorder, personality change due to another medical condition (aggressive type), substance intoxication or withdrawal, ADHD, conduct disorder, oppositional defiant disorder or autism spectrum disorder. “In addition, children ages 6 to 18 years should not receive this diagnosis when impulsive aggressive outbursts occur in context of an adjustment disorder.” However, The DSM-5-TR also suggests that a diagnosis of IED can be made in addition to the diagnosis of ADHD, conduct disorder, oppositional defiant disorder, or autism spectrum disorder if the recurrent impulsive aggressive outbursts are in excess of those usually seen in these disorders and require independent clinical evaluation. Clinical history that is helpful in determining whether the aggressive behavior is better accounted for by another disorder includes whether the aggressive behavior is primarily impulsive and not for secondary gain, does not only occur in the context of a mood disorder, and does not occur only when the individual is intoxicated. If this is not the case, the aggressive behavior is more likely related to another condition.

The DSM-5-TR criteria incorporates criteria that had been considered research criteria previously because studies show that these criteria better identify individuals with elevated levels of aggression, impulsivity, familial risk of aggression, and abnormalities in neurobiologic markers of aggression. Another significant change in DSM-5 IED criteria is the type of aggressive outbursts that should be considered; physical aggression was required in DSM-IV, whereas verbal aggression and nondestructive/noninjurious physical aggression also meet criteria in DSM-5 and DSM-5-TR. In addition, DSM-5 and DSM-5-TR also provides more specific criteria defining frequency needed to meet criteria and specifies that the aggressive outbursts are impulsive and/or anger based in nature and must cause marked distress, impairment in occupational or interpersonal functioning, or be associated with negative financial or legal consequences. Furthermore, because of the lack of research on this disorder in young children and the potential difficulty of distinguishing these outbursts from normal temper tantrums in young children, a minimum age of 6 years (or equivalent developmental level) is required. Finally, especially for youth, the relationship of this disorder to other disorders (e.g., ADHD, disruptive mood dysregulation disorder) has been further clarified.

Table 24.1–1.
DSM-5-TR Diagnostic Criteria for Intermittent Explosive Disorder (American Psychiatric Association, 2013)

A. Recurrent Behavioral outbursts representing a failure to control aggressive behavior, as indicated by one of the following:
   1. Verbal aggression (e.g., temper tantrums, tirades, verbal arguments or fights) or physical aggression toward property, animals, or other individuals, occurring twice weekly, on average, for a period of 3 months. The physical aggression does not result in damage or destruction of property and/or physical assault involving physical injury to animals or other individuals.
   2. Three behavioral outbursts involving damage or destruction of property and/or physical assault involving physical injury to animals or other individuals occurring within a 12-month period.

B. The magnitude of aggressiveness expressed during the recurrent outbursts is grossly out of proportion to the provocation or to any precipitating psychosocial stressors.

C. The recurrent aggressive outbursts are not premeditated (i.e., they are impulsive and or anger-based) and are not committed to achieve some tangible objective (e.g., money, power or intimidation).

D. The recurrent aggressive outbursts cause either marked distress in the individual or impairment in occupational or interpersonal functioning or are associated with financial or legal consequences.

E. Chronological age is at least 6 years (or equivalent developmental level).

F. The recurrent aggressive outbursts are not better explained by another mental disorder (e.g., major depressive disorder, antisocial personality disorder, borderline personality disorder) and are not attributable to another medical condition (e.g., head trauma, Alzheimer’s disease) or to the physiological effects of a substance (e.g., a drug of abuse, a medication). For children ages 6–18 years, aggressive behavior that occurs as a part of an adjustment disorder should not be considered with this diagnosis.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

The age of onset for IED is in adolescence to early adulthood, ranging from 12 to 21 years of age, and is more common in males than females. There is a substantial comorbidity between IED and other psychiatric disorders, with 81% of individuals with IED meeting criteria for at least one other psychiatric disorder, with the most common comorbid disorders being substance use disorders, disruptive behavior disorders, PTSD, ASPD, borderline personality disorder, anxiety disorders, and major depression. In general, the age of onset of IED precedes that of the comorbid disorders, and aggression scores tend to be highest among those diagnosed with IED and a comorbid disorder versus those diagnosed with one of the above disorders alone or IED alone. Studies have also shown that those with IED are at increased risk for engagement in self-harm behaviors and global emotion regulation deficits. For instance, one study demonstrated greater alexithymia and anger rumination among patients with IED compared to psychiatric and healthy control groups, but interestingly also found higher affective empathy in IED versus healthy controls.

ETIOLOGY

The well-documented case of Phineas Gage points out the importance of the prefrontal cortex in impulsive and aggressive behavior. Gage was a railroad worker who survived after a metal rod was blown through his skull in an accident. Prior to the injury he was an upstanding member of the community and a reliable worker. After the injury he was "…fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires,…."

In a review of the literature on frontal lobe dysfunction and violent behavior, Brower and Price concluded that the literature supports an association between frontal lobe dysfunction and increased aggressive behavior, with focal orbitofrontal injury especially being associated with increased aggression. For an individual patient, if an injury were clearly associated with the aggressive behavior, then by DSM-5 criteria the diagnosis of IED would not be made.

However, many violent patients have a history of head trauma due to the nature of their behavior that is not clearly associated with the onset of aggression. It is also unclear what degree of injury is necessary to increase aggressive behavior, making the diagnosis of personality change associated with a general medical condition (head trauma) challenging to separate from IED. A functional magnetic resonance imaging (fMRI) study in patients with IED showed higher error activity and increased activation in a dorsolateral prefrontal cortex subregion, during a color-word Stroop task, possibly indicating a specific neural correlate of clinically high anger expression. Although more research is needed, the literature clearly supports the association between prefrontal cortex brain dysfunction and impulsive aggressive behavior as seen in IED.

Further biologic evidence indicates that the etiology of aggression and IED may be associated with biologic processes. In one study, inflammatory cytokines were higher among individuals with IED versus healthy controls. Consistent with these findings, a genome-wide methylation study found genetic evidence that biologic processes mediating inflammatory response in the immune system, such as cytokine signaling through the interleukin-3 pathway and GABAergic neuronal differentiation were associated with IED.

A third line of biologic evidence supports alteration of neurotransmitter function and impulsive aggression, with the largest body of evidence supporting a role for the neurotransmitter serotonin in aggression. A number of animal studies associate reduced serotonin function and increased aggression. Reduction in the serotonin precursor tryptophan, lesions of the serotonin cell bodies in the dorsal raphe, and serotonin gene knock-out in mice all increase aggression in animal models. In humans, lower levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) are associated with violent suicide attempts and impulsive aggression;

however, other studies have found no association between 5-HIAA levels and aggression. Further evidence supporting a role for reduced serotonin function leading to aggression in humans comes from studies using behavioral laboratory aggression paradigms. Studies using these paradigms have examined the role of serotonin using a drink deficient in the serotonin precursor tryptophan, which produces a significant reduction in plasma tryptophan levels and a reduction in brain serotonin. Several studies using this method of reducing serotonin have shown that there is an increase in aggression in human subjects after tryptophan depletion. The role of central serotonin function in IED has been examined in a study in IED patients where the authors found that physiologic responses to central 5-HT stimulation with dexfenfluramine (d-FEN) were reduced as a function of aggression (but not generalized impulsivity) in human subjects. The central 5-HT deficits in these individuals have been attributed to abnormalities involving 5-$HT_{2A/2C}$ postsynaptic receptors in the limbic hypothalamus. Likewise, several studies have found a reduction in impulsive aggressive behavior after treatment with serotonin reuptake inhibitors in patients with prominent histories of impulsive aggressive behavior. Another line of evidence suggests a significant inverse relationship between platelet 5-HT transporter levels and aggression in individuals with IED, further supporting the notion that reductions in brain 5-HT function are associated with aggressive behavior, particularly impulsive aggression.

Other factors that have been associated with impulsive aggression include childhood exposure to violence, maltreatment, and neglect. A recent study found that there was significant association between IED and aversive childhood parenting environment comparable to other psychopathologies. Another study by the same group found that physical abuse in childhood was independently associated with IED, with impulsivity and aggression as the mediators of the relationship between physical abuse and IED. Others have shown that IED is associated with childhood exposure to interpersonal traumatic events. It has been suggested that it is possible that a gene-environment interaction may exist where individuals who have certain serotonin gene polymorphisms may be more prone to impulsive aggressive behavior after exposure to childhood maltreatment.

TREATMENT

Pharmacotherapy

Pharmacotherapy has been a mainstay of the treatment of aggressive behavior in hospital emergency rooms for many years. However, this type of pharmacotherapy targets the immediate threat of aggression, where the issue of specificity of the treatment is not as important. For the treatment of IED, where impulsive aggression is a longstanding pattern of behavior, it is not clinically acceptable to sedate the patient in order to reduce the aggressive behavior over the long term. For pharmacotherapy for IED, the target is reduction in aggression without reduction in other behaviors.

Several medications are known to reduce aggression and prevent rage outbursts, including antidepressants (namely selective serotonin reuptake inhibitors, or SSRIs), mood stabilizers (lithium and anticonvulsants), and antipsychotic drugs. Placebo-controlled studies targeting long-term treatment of impulsive aggression with pharmacotherapy date to the work of Sheard, who found that violent young inmates showed a significant reduction in aggressive behavior after treatment with lithium compared to inmates treated with placebo. There is also evidence that lithium has an effect of reducing suicide, as well as impulsive aggression directed at others. The primary difficulty with the use of lithium for the treatment of impulsive aggression is its relatively narrow therapeutic window and side effects, including nausea, vomiting, and polyuria.

A number of anticonvulsants have been shown to reduce impulsive aggression in patients without seizure disorders. Phenytoin has been shown to reduce aggressive acts in inmates with impulsive aggression in placebo-controlled studies at blood levels that would be considered low for the treatment of epilepsy. Valproic acid in various preparations has also been shown to reduce impulsive aggression. Placebo-controlled trials showed that valproate and divalproex significantly reduce aggressive acts in individuals with personality disorders and conduct disorder. For individuals with personality disorders, the effect on aggression was greatest in individuals with highest trait impulsivity, pointing out the importance of impulsivity in the pharmacotherapy of aggression. Other anticonvulsants with some evidence to support an effect on impulsive aggression include carbamazepine and topiramate. To date, the evidence supporting carbamazepine as an antiaggressive agent is mixed, with some positive studies and a larger negative trial. Topiramate has also been shown to reduce aggression in several studies carried out by the same research group.

Because of the link between lower serotonin function and aggression, a number of trials of SSRIs for impulsive aggression have been undertaken, with five double-blind studies showing a significant reduction in impulse aggression in nonbipolar, nonpsychotic patients treated with SSRIs compared to placebo; however, less than a third of patients showed a full remission of impulsive aggressive behaviors. In another placebo-controlled pilot study, administration of lorcaserin, a 5-HT_{2c} receptor agonist, was associated with significant reductions in provoked aggressive responses among individuals diagnosed with IED. However, lorcaserin was voluntarily withdrawn from the U.S. market given evidence of association of long-term administration with increased cancer risk.

As mentioned previously, the use of high-dose antipsychotic agents as a sedative is not clinically acceptable for chronic treatment of aggression due to the lack of specificity and side effects. However, lower doses of newer-generation antipsychotic agents appear to have a specific antiaggressive effect that is independent of the antipsychotic or sedative effect. Although no controlled studies have specifically examined the efficacy of newer-generation antipsychotic medications in IED, a number of studies have shown a reduction in aggression in children and adolescents with disruptive behavior disorders and autism, as well as in adults with dementia. In children and adolescents with disruptive behavior disorders and subaverage intelligence, doses of 0.02 to 0.06 mg/kg/day of risperidone are associated with reduction in a variety of symptoms including irritability, lethargy/social withdrawal, hyperactivity/noncompliance, and aggression. However, studies in this population have also shown higher side effects in the risperidone-treated subjects, including sedation, extrapyramidal symptoms, and weight gain. A contrasting case report of an adolescent with IED observed no significant improvements in aggression with risperidone and sertraline treatment, but following discontinuation of these medications, observed positive changes when carbamazepine was added to an ongoing regimen of aripiprazole.

In older adult patients with dementia at doses of 0.8 to 2.0 mg per day, risperidone has shown efficacy in reducing aggression and agitation. However, the U.S. Food and Drug Administration has determined that there is an increased risk of death in older adult patients with dementia-related psychosis treated with risperidone of between 1.6 and 1.7 times that seen in placebo-treated patients due to a variety of causes, including cardiovascular and infectious etiologies. This has led to a “black box” warning for risperidone related to these potential side effects. The risk of risperidone compared to other medications should be kept in mind in light of a recent study that found no difference in improvement in agitation and aggression between risperidone and citalopram in patients with dementia.

Psychostimulants, particularly methylphenidate, have been shown to be effective at reducing impulsive aggression in conduct disorder and ADHD. However, their use for the treatment of impulsive aggression outside conduct disorder or ADHD is limited due to the abuse potential of these medications, as well as the potential for inducing mania in subjects with bipolar disorder.

Psychotherapy

Cognitive behavioral therapy (CBT) and contingency management have both shown evidence of reducing aggressive behavior in both adults and children. However, the literature on the treatment of IED per se with psychotherapy is limited. A randomized controlled trial compared group and individual CBT for the treatment of IED (n = 45) with a wait-list control group. After 12 weekly sessions, group and individual CBT reduced aggression, anger, hostile thinking, and depressive symptoms, while improving anger control relative to wait-list participant patients, with improvements persisting at the 3-month follow-up. Those who attended individual therapy sessions also reported an improvement in their overall quality of life.

24.2 Pyromania

Taylor A. Ochalek, Ph.D., and F. Gerard Moeller, M.D.

DIAGNOSIS AND EPIDEMIOLOGY

The diagnosis of pyromania requires a pattern of behavior, with multiple episodes of deliberate and purposeful fire setting on multiple occasions. The fire-setting behavior can cause shame to the individual, with one study finding that 38.1% of individuals with pyromania considered committing suicide to stop their fire-setting behavior. There is tension or emotional arousal before the act and relief after the act, similar to OCD and kleptomania. Individuals with pyromania are curious about fires and are fascinated with fire paraphernalia and institutions and people affiliated with the fire departments. There is pleasure or relief when setting fires, or when watching or engaging in its aftermath. In comparison to arson, the fire setting is not done for monetary reasons, to hide a crime, to express a sociopolitical idea, for vengeance, or in response to psychosis or judgment that is impaired by major neurocognitive disorder, intellectual disability, or substance intoxication. The diagnosis of pyromania is not better explained by conduct disorder, a manic episode, or antisocial personality disorder. Pyromania is highly comorbid with other disruptive, impulse-control, and conduct disorders, substance use disorders, gambling disorders, and bipolar disorders.

It is important to differentiate pyromania from other causes of fire setting. Fire setting is a behavior that can be accidental or intentional and is not always a symptom of an underlying psychiatric illness. Fire setting (e.g., playing with matches, lighters) may also occur during childhood due to curiosity and may be part of the developmental process. Assessments for fire setting in children and adolescents include the Children's Firesetting Inventory (CFI), the Firesetting Risk Interview (FRI), the Firesetting Incident Analysis Parent Version (FIA-P), and Firesetting Incident Analysis Child Version (FIA-C). A diagnosis of pyromania is excluded if the fire setting is better explained by conduct disorder, mania, antisocial personality disorder, major neurocognitive impartment, intellectual disability, substance intoxication, or in response to delusions, hallucinations, or a medical condition such as epilepsy.

There is a lack of epidemiologic data on pyromania, but there is data on fire setting without the diagnostic restrictions of pyromania. According to DSM-5, the prevalence of pyromania is unknown, but lifetime fire setting in a sample of U.S. residents 18 and older was found to be about 1.0%. In this sample, Caucasian males aged 18 to 35 years living in the western region of the United States had higher rates of fire setting. The most common comorbidities with fire setting include lifetime alcohol and marijuana use disorders, conduct disorder, antisocial and obsessive-compulsive personality disorders, and the most common motive for fire setting, in general, is revenge and anger. In contrast, pyromania, for which revenge and anger are excluded as causes of fire setting, appears to be quite rare. A study found that only 3.3% of arson recidivists met DSM-IV criteria for pyromania, largely because the majority of the arsonists had committed the act under the influence of alcohol, which is an exclusion criterion in DSM-IV, DSM-5 and DSM-5-TR and in fact, most arsonists do not meet criteria for pyromania. A study of 204 inpatient adults on a psychiatric unit found that 3.4% endorsed current pyromania symptoms, and 5.9% had lifetime pyromania symptoms. What literature does exist about the prevalence of pyromania is in children and adolescents, where prevalence estimates range from 2.4% to 3.5%, with 60% of all fires in large U.S. cities being lit by individuals between 11 and 18 years of age.

ETIOLOGY

Pyromania has been described in the literature for over 200 years, however, the etiology of pyromania is poorly understood. Freud described pyromania as consequence of abnormal psychosexual development. Literature on the origins of pyromania has suggested factors ranging from temperament to environmental factors and parental psychopathology. Other authors have suggested pyromania and the other impulse-control disorders may share a neurobiologic link with substance use disorders. One case describes the onset of pyromania with the use of escitalopram. A single case report found a perfusion deficit in the left inferior frontal lobe on single photon emission computed tomography (SPECT), which resolved after treatment with cognitive behavioral therapy (CBT) and topiramate. Other support for frontal inhibitory dysfunction in pyromania comes from neuropsychologic testing of one subject with pyromania, which found attentional, visual memory, and executive function impairments. However, evidence from a case report suggests that impulsivity and decision-making may not be characteristic of all pyromania diagnoses. In this report, compared to 19 age-matched healthy controls, an adult diagnosed with pyromania demonstrated greater cognitive inflexibility but similar performance on measures of impulsivity and decision-making. These deficits in cognitive inflexibility share features of compulsivity and obsessive-compulsive disorder. Earlier limited studies suggest that pyromania may be associated with lower concentration of norepinephrine and serotonin metabolites 3-methoxy-4-hydroxyphenylglycol (MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

In a recent case study of a 28-year-old with young onset Parkinson disease, a pathogenic variant of the FBXO7 gene was associated with impulse control disorder symptoms, including firesetting behavior, following dopamine agonist and levodopa treatment. This suggests that some individuals may be genetically susceptible to the effects of dopamine on increasing impulse control disorders, including pyromania; however, further research is needed to characterize the genetic underpinnings of pyromania to better inform novel treatment approaches.

There is a lack of data on the development and course of pyromania. Most individuals with pyromania start setting fires in adolescence or young adulthood. The frequency and intensity of fire setting may increase over time or may wax and wane. The course of pyromania is unknown but smaller studies suggest it may be chronic. Pyromania occurs more frequently in males with poorer social skills and learning difficulties.

TREATMENT

There are no controlled clinical trials in the treatment of pyromania, and there are no FDA approved medications for the disorder. Case reports on pharmacologic management of pyromania have been sparse and results have been inconclusive. Some case reports have shown a reduction in pyromania urges and behaviors with SSRIs, lithium, naltrexone, stimulants, topiramate, valproic acid, carbamazepine, antiandrogen medication, clonazepam, and olanzapine. Other reports have shown no improvement in pyromania with pharmacotherapy.

What little literature does exist suggests CBT and other psychotherapies may be helpful. Other successful behavioral therapies for fire setting include aversive therapy, education, relaxation techniques, positive reinforcement, graphing therapy (i.e., a visual representation to enhance understanding of temporal correlations between a fire-setting event and antecedent emotions and events), and fire safety education. One study found that CBT, fire safety education (FSE), and a home visit from a firefighter (HVF) improved fire-setting behaviors in children who had recently set a fire. However, CBT was the most efficacious in reducing fire setting, interest in playing with matches, and fire-related behaviors. Another study, which examined a group CBT intervention (Firesetting Intervention Program for Mentally Disordered Offenders; FIP-MO) among deliberate fire setters demonstrated that the intervention was associated with significant improvements in several treatment areas, such as attitudes and interests related to fire, anger expression, and a better understanding regarding fire safety and understanding personal fire-setting behavior, compared to the treatment as usual group.

24.3 Kleptomania

TAYLOR A. OCHALEK, PH.D., AND F. GERARD MOELLER, M.D.

DIAGNOSIS AND EPIDEMIOLOGY

Kleptomania is one of the least studied of the disruptive, impulse-control, and conduct disorders. As conceptualized in DSM-5 and its text revision (DSM-5-TR), the key diagnostic feature of kleptomania is that the items stolen are not needed for personal use or for their monetary value and are not in response to anger, vengeance, a delusion, or a hallucination (see Table 24.3–1). The diagnosis of kleptomania also includes a sense of tension immediately before the theft and a sense of relief at the time of the theft, similar in structure to obsessive-compulsive disorder (OCD). The individual may hoard or return the stolen objects. Usually, the thefts are not preplanned, and very little attention is given to the consequences of the theft. The urge to steal is ego dystonic and distressing. Subsequently, people with kleptomania experience guilt, depression, and suicide. The emotional stress, jail time, and marital and relationship conflict from shoplifting have been shown to decrease quality of life in individuals with kleptomania. As with other impulse control disorders, the diagnosis of kleptomania is not better explained by conduct disorder, a manic episode, or antisocial personality disorder.

DSM-5-TR lists the prevalence of kleptomania in the general population to be 0.3% to 0.6%. The prevalence of kleptomania in those arrested for shoplifting ranges from 3.8% to 24%. A study of 204 consecutive admissions of psychiatric inpatients found a current prevalence of 7.8% and a lifetime prevalence of 9.3%, implying that the disorder may be more common than previously thought. Some of the underdiagnosis of kleptomania may be related to the fact that the disorder is ego dystonic and patients are embarrassed to discuss their symptoms. The course of kleptomania is chronic with waxing and waning of symptoms. Kleptomania may begin in childhood, adolescence, or adulthood, but commonly begins during adolescence, with an average age of onset of 18.75 years. Kleptomania occurs more frequently in women, with about two-thirds of kleptomania patients being women. Females with kleptomania are more likely to be married, shoplift household items, store stolen items, shoplift at a later age, and have a comorbid eating disorder or other impulse-control disorder. Kleptomania is highly comorbid with compulsive buying, mood disorders, anxiety disorders, eating disorders, personality disorders, substance use disorders, as well as other disruptive, impulse-control, and conduct disorders. The rate of OCD in kleptomania has ranged from 6.5% to 60%. Due to the high comorbidity between OCD and kleptomania, it has been suggested that kleptomania may be a variant of OCD.

Table 24.3–1.
DSM-5-TR Diagnostic Criteria for Kleptomania (American Psychiatric Association, 2013)

A. Recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value.
B. Increasing sense of tension immediately before committing the theft.
C. Pleasure, gratification, or relief at the time of committing the theft.
D. The stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination.
E. The stealing is not better accounted for by Conduct Disorder, a Manic Episode, or Antisocial Personality Disorder.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

Kleptomania is associated with increased impulsivity, with a study showing that patients with kleptomania had higher scores on the Barratt Impulsiveness Scale, greater cognitive impulsivity, and greater sensation seeking in comparison to a psychiatric group without impulse control or substance use disorders. Furthermore, individuals with greater severity of kleptomania symptoms have been shown to demonstrate more executive functioning impairment on the Wisconsin Card Sorting Test (WCST), greater cognitive impulsivity, and greater sensation seeking.

Higher impulsivity may also be associated with shoplifting-related legal consequences among individuals with kleptomania. One study conducted on 107 adults with kleptomania reported higher impulsivity scores on the Eysenck Impulsiveness Questionnaire (EIQ) among those with at least one shoplifting-related arrest compared to those without a shoplifting-related arrest history. In contrast, another study did not observe an association between impulsivity and kleptomania symptom severity on the EIQ and found that lower ADHD symptoms were actually associated with greater symptom severity.

In a study that examined the clinical correlates of kleptomania symptom severity among 112 adults with kleptomania, comorbid diagnosis of OCD or eating disorder (i.e., anorexia nervosa, bulimia nervosa), a higher frequency of stealing-related urges and feelings of excitement, stealing from relatives, and a lower prevalence of family history of substance use disorder(s) were significantly associated with greater symptom severity.

ETIOLOGY

The Swiss physician Mathey described kleptomania as early as the 19th century, but little is known about the etiology of kleptomania. There have been case reports of kleptomania being associated with head trauma, frontal lobe lesions, cortical atrophy, dementia, and hypoglycemia secondary to insulinoma. On diffusion tensor imaging, there is reduced fractional anisotropy in the inferior frontal white matter in patients with kleptomania, implying that the disorder may be associated with subtle white matter pathology. Similarly, in a neuroimaging case study, an adult with overall normal neurocognitive functioning diagnosed with kleptomania, OCD, and CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) exhibited hyperactivity in the right ventral striatum region, and CREST-related white matter damage in the orbitofrontal region. This indicates that white matter lesions in the orbitofrontal brain region may play a nuanced role in the etiology of kleptomania. Another study found that although as a group patients with kleptomania did not show deficits on neuropsychological testing, the severity of illness was associated with impairment in executive functioning.

Data is lacking and limited on the genetics of kleptomania. A study found that individuals with kleptomania had more first-degree relatives with alcohol use disorders compared to controls. Treatment studies (discussed below) have focused on medications that target serotonin and dopamine, as well as the opioid and glutamatergic neurotransmitter systems; however, there is not a large body of data showing these neurotransmitters play a role in kleptomania, although there are higher rates of OCD in relatives of individuals with kleptomania compared to the general population, suggesting a potential common neurobiology.

TREATMENT

Limited data exist to guide treatment options. To monitor results of treatment, various scales have been used. Although the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) is not a validated rating scale for kleptomania, it has been used to monitor treatment response in kleptomania. The Kleptomania Symptom Assessment Scale (K-SAS), a self-report measure, has been shown to have adequate psychometric properties in assessing changes in behaviors, urges, and cognition during treatment.

Pharmacotherapy

Due to the guilt associated with the behavior, most individuals with kleptomania seek treatment after being arrested. Pharmacologic studies for kleptomania have been limited to mostly case reports and case series. Selective serotonin reuptake inhibitors have been tried based on the notion that kleptomania may be an obsessive-compulsive spectrum disorder. However, case reports have shown mixed results for SSRIs, with some reports of improvement, but at least one report described patients who developed kleptomania during treatment with SSRIs. There have also been case reports of lithium and topiramate reducing urges to steal in kleptomania. An open-label trial found that the mu opiate receptor antagonist naltrexone reduced urges to steal and stealing behavior in kleptomania. In an individual case study of a patient with intellectual disability, aggressive behavior, and kleptomania, naltrexone administration decreased both stealing behavior and aggression. In another open-label trial, the N-methyl-D-aspartate (NMDA) receptor antagonist memantine reduced urges to shoplift and shoplifting behavior, along with improving impulsivity, mood, anxiety, and psychosocial functioning. In one of the few placebo-controlled trials in the treatment of kleptomania, there was a significant effect of naltrexone on kleptomania symptoms, with 66% of the patients that received naltrexone achieving remission, whereas 7.7% of those receiving placebo reported symptom remission. The only controlled trial of antidepressants in the treatment of kleptomania found no benefit of escitalopram in the treatment of kleptomania.

Psychotherapy

There is little literature regarding the treatment efficacy of psychotherapy for kleptomania. Case reports and case series suggest that cognitive behavioral therapy (CBT) approaches may be helpful. One recent case report demonstrated the initial feasibility of combining exposure and prevention therapy (ERP) with CBT and biofeedback in reducing stealing behavior and improving kleptomania symptoms. Findings demonstrated that ERP + CBT reduced kleptomania symptoms and sympathetic nervous system arousal (measured via galvanic skin response) from baseline; however, the addition of naltrexone did not provide further clinical benefit. Although biofeedback offers an innovative and individualized approach to support psychotherapy, larger-scale studies are needed to examine its reliability and generality.

Adjustment Disorders

Jeffrey W. Katzman, M.D., and Cynthia Geppert, M.D., Ph.D., D.P.S., M.A., M.P.H., M.S.B., M.S.J., F.A.C.L.P., D.F.A.P.A., F.A.S.A.M., H.E.C-C.

The diagnostic category of adjustment disorders (ADs) is widely used among clinicians in practice. The construct is often criticized for lack of scientific support, though research in the area has increased in the last 5 years, and world events have demonstrated its clinical utility. The DSM-5 classification of AD among a group of stress response syndromes underscores that the central heuristic feature of AD is the linkage between the development of symptoms to an external stressful event. The event often involves financial, legal, or relationship difficulties or a new medical diagnosis. The adjustment disorder construct is often criticized for lack of scientific support, though interest in the study of this diagnosis appears to have grown over the past 5 years. The diagnosis of AD strays from the general phenomenologic approach of the DSM. The fifth edition of the diagnostic and statistical manual does not provide observable symptom criteria, such as the familiar list of signs and symptoms that characterize the other major diagnostic categories.

The link between an environmental stressor and symptom formation is consistent with paradigms many clinicians utilize and with the health beliefs of the general public about the adverse effects of stress. This may account somewhat for the appeal of this diagnostic category for patients and practitioners alike. The development of psychophysical symptoms in response to distressing experiences is a recognized part of the human condition, making the diagnosis often less socially stigmatizing than other psychiatric disorders. Furthermore, medical insurance carriers historically have not considered the diagnosis as a preexisting condition in the same way as they have labeled other psychiatric disorders such as major depression. This distinction frequently leads clinicians to use the diagnosis to protect patients from future discrimination in employment matters and medical, life, and disability insurance applications.

Ultimately, it is important to note that, despite the historically problematic nature of this clinical entity, the AD diagnosis was ranked seventh of 44 diagnostic categories by psychiatrists in a 2018 study by the World Health Organization, inquiring about the most frequent diagnoses used within a 1-week period. In a similar worldwide study in 2013, thousands of psychologists worldwide asked the same question and ranked the AD diagnosis ninth. Yet, in these same studies, the AD diagnosis ranked in the lowest percentile of ease of use or goodness-of-fit in clinical practice.

COMPARATIVE NOSOLOGY: DSM

Despite the clinical appeal of this category of diagnoses, ADs as a diagnostic entity have been seen as problematic for a number of reasons, and the reconfiguration of DSM-5 has done little to address these problems. The diagnostic criteria describe a syndrome in which a stressful event leads to the development of a symptom complex. However, within the diagnostic construct, there are no qualitative or quantitative criteria to determine what stressor meets the diagnostic threshold as there is for post-traumatic stress disorder (PTSD). Similarly, the symptom complex that develops has been criticized as lacking specificity, which is the obvious drawback of its generalizability. Unlike DSM-5 (and its text revision, DSM-5-TR), ICD-11 has to some degree addressed this problem, thereby creating a notable difference in nosology between the two primary classification systems. This shift in definition in ICD-11 raises some particular concerns regarding research on AD, as the DSM and ICD-11 are describing potentially different psychiatric entities at this point. Critics also contend that the temporal course between the stressor and the development of symptoms lacks rigorous scientific evidence. Furthermore, it is difficult in clinical practice to directly link an event to the development of a symptom complex. These issues have raised questions about the diagnosis in general and have no doubt contributed to the lack of academic investigation. Perhaps the greatest dilemma in considering this diagnosis like others in the trauma and stress-related DSM-5 category involves the question as to why some individuals develop symptoms in response to a stressful event while others do not, making AD a perfect vehicle for studies of the often-underappreciated role of resilience in the face of stressful life circumstances.

The entire formulation of an AD has been impugned with disparaging designations such as a “wastebasket” or “afterthought” diagnosis. Despite recognition among experts working on DSM-5 of the need to clean up the diagnosis of AD, the final version left the wastebasket full. Academic literature on AD identifies three main nosologic weaknesses. The first and most serious objection is that the diagnosis is yet another manifestation of the increased medicalization of life problems, as well as the hegemony of biologic models in psychiatry at the expense of social, psychological, cultural, and spiritual conceptualizations and responses to illness. The second critique points to the diagnosis’ failure to present a consistent, coherent, and clear explication of the essential relationship between an external stressor and internal diathesis. While the criteria require the stressor to precede the development of symptoms in a causative manner, no specific symptoms, duration, nature, or magnitude of stressor that would trigger the development of AD has been delineated. It is extremely difficult in clinical practice to infer causality from the stressor to the development of symptoms. A clinician must then assess whether an individual’s symptoms are above and beyond what would be considered normal for that particular stressor. This raises one of the central philosophical issues in postmodern psychiatry: where normality ends, and pathology begins.

The third “wastebasket” criticism refers to the use of AD for clinical presentations that fail to meet the criteria of other psychiatric diagnoses—particularly major or minor depressions. Similarly, the predictive validity of the diagnosis has been criticized in that many initial diagnoses of AD are later changed to another primary affective, substance use, or personality disorder. Frequently the main factor in that change is the duration of the disturbance and not the degree of severity. Once the temporal threshold has been met for another anxiety mood or even trauma disorder, the diagnosis is changed, yet the arbitrariness of these time periods is well-recognized. Claiming AD is transformed suddenly into another entity after 2 weeks or 2 months is not sound science. However, defenders of the diagnosis argue that the nosologic problem lies more with the vague, abstract, and over-general formulation of the criteria than the actual concept of a time-limited maladaptive reaction to stress. This has begun to be addressed in the most current version of ICD-11. Despite these deficiencies, the diagnosis has had an enduring clinical and heuristic value that warrants a more nuanced understanding of its utility and meaning.

HISTORY

ADs as a personal reaction to an environmental or social stressor are likely universal phenomena, which have occurred in all historical epochs and cultures. A recent author suggests that the first recognizable clinical description of an AD and its appropriate treatment is in the 11th-century writings of the Islamic physician–philosopher Avicenna. Historically, DSM has always included some version of a diagnostic category involving an acute psychological response to an environmental stressor. The initial impetus for this came from documentation of severe wartime stress seen in World War II, as well as through the evolution of crisis intervention theory and practice. DSM-I, published in 1952, described the category of Transient Situational Personality Disorder. Within this category were the subtypes of gross stress reaction, adult situational reaction, adjustment reaction of infancy, adjustment reaction of childhood, adjustment reaction of adolescence, and adjustment reaction of late-life. It is notable that even the first appearance of this diagnosis displays an overlap in the diagnostic symptoms between the concepts of a stressor, depressive and anxious affect, and one’s personality.

The diagnosis was modified somewhat in DSM-II, which changed the concept to transient situational disorder. This category was reserved for “more or less transient disorders of any severity (including those of psychotic proportions) that occur in individuals without any apparent underlying mental disorders and that represent an acute reaction to overwhelming environmental stress.” DSM-II provided similar developmental subtypes to DSM-I, with the exception that the subtypes of gross stress reaction and adult situational reaction were eliminated.

DSM-III introduced the formal diagnosis of AD. The developmental periods of the earlier diagnostic systems were removed. Instead, the subtypes of AD were categorized based on the predominant affective experience. These included AD with depressed mood, anxious mood, mixed emotional features, disturbance of conduct, mixed disturbance of emotions and conduct, work inhibition, withdrawal, and atypical features. DSM-III-R retained these diagnostic subtypes and added an additional one involving physical complaints. DSM-III-R also specified that symptoms of an AD could not exceed 6 months.

DSM-IV modified the diagnosis of adjustment disorder in several ways. The subtypes of mixed emotional features, work inhibition, withdrawal, and physical complaints were eliminated. The stressor was allowed to persist for an indefinite period of time. A descriptor of chronicity was specified, whereby symptoms persisting for greater than 6 months were deemed chronic.

DSM-5

DSM-5 did not make substantial changes to the actual diagnostic criteria for AD. A key change in classification did occur that, in the view of one author, “represents a major shift in thinking and is the most significant change since its introduction in the DSM-III.” AD is now classified with reactive attachment disorder, disinhibited social engagement disorder, PTSD, acute stress disorder, other specified trauma- and stressor-related disorders, and unspecified trauma- and stressor-related disorders in a newly delineated category of Trauma- and Stressor-Related Disorders. In some measure, this reorganization settles, at least for the time being, the long historical debate about whether AD belongs in the family of mood, anxiety, or stress disorders. The authors of DSM-5 chose to emphasize most strongly the nature of AD as one of a range of human responses to stress and trauma and to conceptualize the disturbances of mood, anxiety, and conduct that constitute the established subtypes of AD as varied aspects of the stress–trauma response spectrum.

In prior versions of DSM with a multiaxial diagnostic system, AD was coded on Axis I, with the specific stressor coded on AXIS III or IV on the problematic axial system that DSM-5 has eliminated. Under that classification schema, the diagnosis of AD could not be assigned if an Axis I disorder had already been diagnosed. This restriction generated further obfuscation of the diagnostic picture, which in turn could lead to inappropriate treatment recommendations. In this way, AD was and continues to be considered a subthreshold diagnosis within DSM, as it is not coded in the presence of another Axis I diagnosis.

DEFINITION

ADs are a diagnostic category characterized by an emotional response to a stressful event. The stressors involved for the other diagnoses in the DSM-5 category of Trauma and Stress-Related disorders have criteria, which are fairly well-delineated. As discussed above, there are currently no such criteria for the stressor of an AD. Typically, the stressor involves financial issues, a medical illness, or a relationship problem. The symptom complex that develops may involve anxious or depressive affect or may present with a disturbance of conduct. There is little specificity to qualify these symptoms other than an excess of what would be expected from the particular stressor or significant social or occupational impairment. By definition, the symptoms must begin within 3 months of the stressor and must remit within 6 months of removal of the stressor. The symptom complex must not qualify for another Axis I condition. Bereavement is an exclusion. The subtypes of AD did not significantly change in DSM-5: AD with depressed mood, anxious mood, mixed anxiety and depressed mood, disturbance of conduct, mixed disturbance of emotions and conduct, and unspecified type. Recent research has questioned the value of maintaining these different categories of AD, as there appears to be more in common between individual subtypes than evidence for distinct diagnostic entities. Glaesmer et al. demonstrated that the correlation between different subtypes was extremely high, suggesting that these subtypes were not adequately distinguishable. This finding has been replicated in more recent studies, which all found that subtypes of DSM-5 were highly intercorrelated, suggesting that there is insufficient evidence at present to substantiate the existence of distinct subtypes of AD. In an outpatient sample, no differences in sociodemographics, comorbid diagnoses, or lifetime history of the disorder could be found in groups diagnosed with the anxious and depressive subtypes of AD. The author raised the question of collapsing these subtypes into one diagnostic entity.

STRESSOR CRITERIA

DSM-5-TR criteria for AD rely first and foremost on the presence of a stressor. “The presence of emotional or behavioral symptoms in response to an identifiable stressor is the essential feature of adjustment disorder.” The explanatory material accompanying AD criteria in DSM-5-TR attempts to sketch the nature of the stressors, yet the contours remain unclear, especially when compared with the relatively sharper profile of the trauma of PTSD or the obvious stressor in bereavement. The text contains multiple examples of this ambiguity. For instance, the stressor can be single, like the loss of a significant relationship, or multiple, such as combined employment and marital problems. The stressor can be recurrent, such as a construction worker who cannot find work during the winter, or continuous, most commonly with AD from a chronic illness. In contrast with the individualistic focus of most of the disorders in DSM, AD can be familial or communal in its impact, as can PTSD. The implicit developmental triggers of AD—well known to clinicians—are made explicit, such as the "empty nest syndrome" or a child going off to college. This leaves the clinician to determine whether any particular stressor could lead to the development of a stress response for a specific person. The vast range and variance in putative stressors are quite large, and it is difficult to reasonably believe that such a divergent group of human experiences would lead to a similar psychological experience.

SYMPTOMS

The description of AD symptoms that develop in response to these diverse stressors is fairly vague in DSM-5. They are either a reaction that would be greater than expected given cultural and contextual factors, or they significantly impair social, occupational, or other domains of functioning. The implication of the current DSM-5 criteria is that there is an expectable reaction to a particular stressor. Clinicians are left to determine what response might be "expectable" to any identifiable event. Any such assessment of the response would be influenced by the personal history, values, and culture of the individual examiner and the patient.

TEMPORAL COURSE

DSM-5 did not change the time course of AD found in prior versions of the manual. The onset of symptoms of AD must be within 3 months of a stressor and the resolution of symptoms within 6 months of the termination of the stressor unless another major psychiatric diagnosis preempts AD. There is some evidence to support the idea of symptom development closely following the time course of the stressor. Two studies have demonstrated the close temporal relationship between a stressor and symptom formation. In one study of children with a new diagnosis of insulin-dependent diabetes, nearly one-third developed ADs. The highest risk period was in the first month following diagnosis, and 31 of 33 children had developed symptoms within the first 3 months following the diagnosis of diabetes. The current criteria for AD in ICD-11 capture this idea, in that, unlike DSM-5, symptoms must develop within 1 month of the onset of the stressor.

It is likely that symptom formation in some individuals might come with a considerable time lag. The "with delayed expression" specifier for PTSD allows for the development of symptoms 6 months or later after the time of the stressor. DSM-5 includes a similar exception under the "Other Specified Trauma- and Stressor-Related Disorders" that lists a presentation of AD with delayed onset 3 months after a stressor. The literature confirms the potential temporal variation in symptom formation from the onset of the stressor. One study examined the timing and number of life events occurring in the year before the onset of emotional disorders in school-aged children in an outpatient clinic. Thirty percent of cases did not develop symptoms until 6 months to 1 year following the undesirable event. Children who experienced multiple negative life events were more likely to have less time between a stressor and symptom formation.

The diagnosis of AD specifies that the symptoms do not persist for more than 6 months once the stressor—or its consequences—has terminated. There is a DSM-5 diagnosis included in the Other Specified Trauma- and Stressor-Related Disorder classification for an AD-like disorder with a duration of symptoms prolonged for greater than 6 months past the point where the stressor is no longer active. It is often extremely difficult for a clinician to gauge when a stressor is no longer impacting an individual. In many cases, stressors leading to this diagnosis, such as chronic illness, retirement, or marital tensions, may last indefinitely. Rather, the meaning of the stressor to the individual may change over time, for instance, with a support group or couples' therapy. Scholarship supports the notion that emotional symptoms can linger for quite some time. A study compared the long-term mental health effects in adults suffering from two different community stressors (the Three Mile Island accident and widespread unemployment due to layoffs). Symptoms remained elevated for as long as 42 months after both stressors. It is unclear, however, if this data shows that an event can lead to persistent emotional responses or whether the event itself is ongoing and thus continues to impact an individual. More recent studies suggest that symptoms of AD may become chronic for nearly one-third of individuals.

A study at the University of Michigan captures the enduring nature of stress. The research identified increased stressors, including marital breakups and stress, and financial issues as lasting symptoms following the September 11, 2001, terrorist attacks in a city 600 miles from the actual events. In addition, there was an increased rate of medically serious suicide attempts in the 2-year period following the attacks compared to the previous 2 years. These results speak to the potential chronicity of stress following a single traumatic event and may be applicable to the development of chronic AD as well.

ICD

The *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) also contains a category of ADs. ICD-11 revised its ADs nosology with this version. With his change, ICD-11 aims to make the AD criteria more specific and amenable to academic research, though it now describes a syndrome fairly distinct from that described in DSM-5. The diagnosis had long been similar to the DSM entity in outlining the development of psychological symptoms following a stressor. However, in ICD-11, the symptoms must appear within 1 month of the stressor rather than the 3-month temporal course of DSM-5. Like DSM-5, the ICD-11 criteria require that symptoms must not persist for greater than 6 months after the removal of the stressor. While DSM-5 removed the acute and chronic specifiers for the subtypes of AD, ICD-11 includes a category of Prolonged Depressive Reaction for AD-like symptoms that persist for up to 2 years.

The ICD-11 makes a major shift from ICD-10 and from DSM-5 in the description of symptoms. These are no longer simply vague emotional or behavioral symptoms but rather involve the specific category of preoccupation with the stressor. This may take the form of either excessive worry about the stressor or recurrent and distressing thoughts about the event reminiscent of illness anxiety disorder and PTSD in DSM-5. The ICD-11 symptoms must also include the idea of a “failure to adapt.” This involves significant impairment in function in at least one important life domain. This is different from DSM-5, which suggests that symptoms may cause either a significant impairment in function *or* disproportionate distress given the severity of the stressor. Interestingly, thus far, it is unclear if this addition of more specific symptoms of AD in ICD-11 stands up to rigorous research. An analysis by Kazlaukas et al. of 10 studies using the Adjustment Disorders New Module (ADNM), based on the ICD-11 definition, suggests that empirical data do not provide sufficient evidence for the current ICD-11 symptom structure. While ICD-11 provides greater symptom specificity, it retains the status of a subsyndromal diagnosis as it is not made in the presence of another psychiatric condition, relegating it generally to the category of a minor psychiatric condition. Nevertheless, the presence of greater symptoms specificity has led to more European research in the area of AD, with the emergence of 10 new studies in the 3 years following the release of ICD-11 criteria in 2016. It is likely that this encouraging trend will continue to facilitate additional research in the area of AD specificity.

RELIABILITY

The literature contains mixed information about the reliability of the AD construct. The results of the UK-World Health Organization (UK-WHO) study of the reliability of the ninth revision of International Statistical Classification of Disease categories in children and adolescents were consistent with this. The interrater reliability for

ADs was 0.23; this was lower than for many other categories. The clinical relevance of poor reliability was underscored in a study that examined the concordance rate between an initial diagnosis of AD given by a house officer and a subsequent diagnosis by a consulting psychiatrist. Fifty percent of the inpatients with AD actually had delirium.

VALIDITY

There is a growing body of research that supports the content and predictive validity of the diagnosis. Content validity has been demonstrated through several studies that differentiated AD from major depression on the one hand and normal reactions to stress on the other. It should be noted that results from the European Outcome of Depression International Network (ODIN) research failed to demonstrate content validity in that it identified no variables that might distinguish AD from depression.

For instance, a study of consultation cases in the medical setting found that patients given the AD diagnosis also had higher ratings on Axis IV, lower illness severity, and were more likely to be improved at the time of discharge.

Predictive validity was demonstrated through a study involving a group of 2,078 male Navy-enlisted personnel diagnosed with transient situational disturbance. This proved to be a less disabling diagnosis in terms of chronicity, length of hospitalization, and ability to return to a previous job than any other psychiatric condition diagnosed. The predictive validity of the diagnosis was also demonstrated in a large study of adult inpatients. The investigators sought to determine whether patients with AD shared a similar prognosis at 5 years. Seventy-nine percent of adults in the study were well at 5-year follow-up. The diagnosis was not as predictive for adolescents with 57% well at 5 years. The authors suggest that the adult cohort’s good prognosis implies specific characteristics of the AD group, and that indicates the diagnosis carries with it a prediction of recovery at 5 years. The cohort of children in the sample, however, does not exhibit this same predictive validity.

A study of Danish conscripts supports both content and predictive validity. Subjects diagnosed with AD showed a steady increase in symptoms of depression, sleep, personality problems, and somatization from the time of entering the service until discharge. Fourteen days after discharge, scores on all symptom domains were comparable to those at entrance into the military, and 1 year later, except for a higher depression score, subjects were comparable to controls. Subjects with AD also differed from general conscripts on personality profiles at enrollment, having more adverse family events, depression, and personality problems.

Historically, AD was not included as a potential diagnosis on most structured diagnostic measurements, including The Schedule for Clinical Assessment in Neuropsychiatry (SCAN; Wing et al., 1990), Structured Clinical Interview for DSM-IV (SCID; First et al., 2002), and the Mini-International Neuropsychiatric Interview (MINI; Sheehan et al., 1998). However, new formal assessment measures for AD have been developed. The Diagnostic Interview for Adjustment Disorder (DIAD) is a structured interview based on DSM AD criteria. It includes 29 items that assess symptoms associated with a stressor and delineates the distress and impairment experienced as a result of these. Initial data demonstrates “moderate to good” construct validity. The ADNM developed by Glaesmer et al. in 2015 is based on three groups of symptoms originally proposed for the ICD-11 diagnostic revision. These include symptoms of intrusion, avoidance, and failure to adapt. While this scale likely needs further exploration, it has been applied more recently to community samples to identify the prevalence of AD. Validation studies of this instrument have demonstrated good levels of diagnostic specificity and sensitivity, with shorter forms also demonstrating high-construct validity.

CULTURAL PERSPECTIVES

An interesting discussion is posited regarding the utility of the AD diagnosis through the lens of cultural anthropology. DSM-5 cautions the clinician attempting to decide whether or not a given response is disproportional to the expected reaction to a stressor to "take into account the external context and the cultural factors that might influence symptom severity and presentation." This perspective considers the evidence that most cultures have identified a psychological phenomenon whereby an individual is stressed to the point of symptom development. This parallels the lay concept of a "nervous breakdown" within a particular cultural setting. In this sense, the ADs share features with other culture-bound syndromes such as Susto, Koro, and Arctic Hysteria in that they all describe the development of a set of symptoms following a particular stressor. DSM-5 includes these and other culture-bound syndromes in the category of Other Specified Trauma- and Stressor-Related Disorders and specifically mentions *Ataque de Nervios.* The particular cultural presentation of an AD will be affected by: (1) the nature, intensity, and meaning of the stressor in question; (2) the nature of the modal personality configuration of the people involved—which includes style and/or rules about behavior and emotional expression; (3) idiosyncratic features of the self in question; and (4) the meaning that AD has in the culture. The individual is first treated within the family and other social support networks. When this fails, the event is inevitably medicalized in some fashion.

The universality of a maladaptive reaction to disturbing but less-than-catastrophic traumas is shown in studies in non-Western countries.

Studies with refugees, immigrants, victims of torture, and expatriate populations suggest that cultural conflict, problematic acculturation, social or economic displacement, or political disenfranchisement or persecution are all contemporary stressors that may lead to the development of AD in a global context.

Experiences of black persons and people of color, as well as marginalized populations in societies, put them at greater risk for the development of AD. Around the world, individuals of diverse religious, cultural, ethnic affiliations, as well as LGBTQ individuals, face discrimination and often violence. A long history of police brutality toward African Americans in the United States reached a nadir in 2020 with the tragic deaths of George Floyd, Breonna Taylor, and Ahmaud Arbery. They, among many others, are the victims of 400 years of mistreatment of black people, reflecting rampant structural racism in America that has led to protests and cries to defund the police. Such cultural inequities can lead to an experience of grief and anger that understandably may impact other areas of one's life. There is a heavy burden of economic and political injustice and health disparities that persons of color have long experienced in American society. It becomes critical for persons of privilege to begin to understand the experience of these disenfranchised members of their own communities and begin to take action to curb such inequities.

Modern medical culture often utilizes the AD diagnosis as a means of simultaneously destigmatizing and legitimatizing psychic distress. No other diagnostic category in DSM is so well-suited to communicating both to patients and third parties that the dysfunction in questions is the result of an understandable, if an exaggerated reaction to external events rather than an internal dysfunction, whether biologic or psychosocial. Third parties, including health and life insurance carriers, employers, and family members, often look at this diagnosis as a nonrecurring phenomenon with a generally good outcome. AD enables a clinician to use the current language of health care delivery to indicate that the patient is significantly impaired to warrant clinical attention and hence payment for services rendered. It also underscores the assumption in Western medical culture that maladaptive forms of distress necessarily represent clinical diagnostic entities and, as such, can be seen as yet another form of the medicalization of distress.

A 46-year-old second-year pediatric resident Dr. S receives a negative evaluation from her faculty supervisor and is put on academic probation pending her ability to show significant improvement in her clinical performance. Dr. S had been very successful in her medical career until she sustained a back injury in a biking accident, and one of her sons was diagnosed with bipolar disorder. These added pressures significantly impaired Dr. S's ability to function as a resident physician. After the evaluation, she was unable to get out of bed and often called in sick. Dr. S's mood was irritable and depressed, and she found herself unable to concentrate or make decisions either at work or home. When her children found her crying one afternoon, Dr. S realized she needed help and sought assistance from employee health. The therapist who assessed her indicated she felt the patient was suffering from major depression. The patient was quite concerned that this diagnosis would suggest to her program director that she was not fit for duty. She thus requested the therapist diagnose her with a less serious condition. The therapist agreed to use the DSM-5 criteria for AD in her clinical notes and for billing purposes.

EPIDEMIOLOGY

Historically, few studies examined the prevalence of AD in community samples, underscoring its marginal and ambiguous status in the outpatient diagnostic repertoire. Neither the Epidemiologic Catchment Area nor the National Comorbidity Study included AD in the survey instruments. One exception to the exclusion of AD in epidemiologic research is the European ODIN study, which was a cross-sectional two-phase community assessment using first the Beck Depression Inventory and then the SCAN, one of the few structured instruments to include AD. Less than 1% of the subjects were diagnosed with AD, and the rate varied from country to country. The discrepancy between these findings and almost all previous studies raises further questions regarding the reliability and validity of current diagnostic criteria, not just for AD but also for all the depressive disorders bordering AD. Further epidemiologic information on AD can be gleaned from an examination of specific populations exposed to stressful events. One of the largest studies looking at the prevalence of ADs in a clinical population examined patients on entry to the clinical services of the Western Psychiatric Institute. Intake involved a diagnostic assessment of over 11,000 individuals of all ages using a semistructured assessment form and DSM-III criteria sheets. Ten percent of the sample was found to have ADs, making it the second-largest diagnostic category. In children and adolescents under 18 years of age, over 16% had ADs. In adults, the female-to-male ratio was approximately two-to-one. In children, there was only a slight preponderance of females with the diagnosis.

However, more recent studies employing more sophisticated scales looking for the presence of AD have estimated a point prevalence closer to 2% of the general population. It is highly likely that the unprecedented global stressors of the last decade, including the COVID-19 pandemic, the resultant global economic collapse, a rising consciousness regarding climate change and the imminent threat to our environment, and increasing political polarization threatening democracy will lead to an increase in the prevalence in 2020 and the years following. In a population over 65, the prevalence rate was found to be 2.3% using this scale. In a German study using the new ICD-11-based ADNM, rates ranged from 9% to 1.4%, varying on the version of the scale used. Rates of AD have been found to be much higher using this scale in specific populations. In postconflict regions, the prevalence of AD using the ICD-11 concept ranged from 6% to 40%. This lends further support for the current move to include ADs in the DSM-5 category of Stress Response Syndromes.

Bachem and Casey describe various settings in which the rates of AD are much higher than the general population. While no studies have been conducted in primary care settings or consult-liaison environments using the revised ICD-11 criteria, these areas have historically seen more frequent presentations of AD. In consult-liaison services, the diagnosis of AD using DSM has historically been approximately 12%, though this number appears to be declining in favor of the diagnosis of Major Depressive Disorder in this cohort, perhaps due to the greater intensity of study of the latter. A multisite study in consultation psychiatry services in the United States, Canada, and Australia found a diagnosis of AD among 12% of all consultations, with another 11% identified as having the potential of an AD diagnosis. Other C/L service studies have described a prevalence of nearly 30%.

Decades of research have found a higher prevalence of adjustment disorder in patients in the medical setting—especially patients with cancer and those receiving palliative care. One meta-analysis of 70 studies showed a rate of 19.4% of patients with AD, compared with 16.3% with MDD, and the diagnosis of AD was nearly three times as common as MDD in the medically ill.

In a study of 107 patients with head and neck cancers, 14 (12.1%) had a diagnosis of AD. In another study of 55 women following a first recurrence of breast cancer, 19 (35%) were diagnosed with AD.

Other specific unfortunate life events put individuals at particular risk for the development of an AD. One such group is described in a Danish study examining the prevalence of adjustment disorder in women who have experienced a stillbirth—loss of a fetus anytime following 22 weeks. This large-scale study showed that women had a transient increased risk for psychiatric hospitalization within the first month following fetal death. The most likely diagnosis in this group was an AD. Another such group involves individuals who have been incarcerated.

Finally, one must consider the emergence of two dramatic global public health events, climate change, and the COVID-19 pandemic, as triggers for the development of AD on a far wider scale than has ever been seen in clinical care. Research is already suggesting that worldwide climate change is increasing rates of mental health disorders, as well as exacerbating existing conditions. Events such as uncontrolled wildfires in Australia and California with the devastation of wildlife and ecosystems, as well as human habitation, flooding, and earthquakes have left many physically displaced and facing the loss of loved ones and their health and livelihood. The destruction of farms due to droughts around the world has led to famine and disease. For many, a stable sense of self comes through connection with their environment and its predictable rhythm of the seasons. These climate disasters not only result in food scarcity: They also rob especially rural populations of the very environmental conditions that promote a sense of self and instill purpose. The literature describes presentations of PTSD, depression, suicidality, anxiety disorder, and substance use disorders related to these catastrophic changes in climate. AD is generally not screened for such studies, yet it is probable that these stressors have similarly driven up the incidence of this diagnosis. Such mental health issues may be short-lived if the stressor is resolved, or they may lead to a chronic form of adjustment disorder in the presence of ongoing environmental distress or even devolve into a more serious diagnosis. Pathways to mental health problems from climate-related events include economic, migratory, and community structure changes leading to shame, uncertainty, and potentially depression. Climate change may displace as many as 150 million people, and the maintenance of social supports may outweigh fiscal support in enabling postdisaster recovery. There is also emerging evidence that suicidality itself may be influenced by climate-related change, including linkages between suicide and air pollution, drought, and rising temperatures.

A 58-year-old male, Mr. J, presents to his local internist in Northern Canada explaining that his farm has been nonfunctional in the past 3 years due to alternating drought and floods from climate change. Mr. J is facing severe economic hardships, having difficulty paying the mortgage on the property that has been in his family for three generations. He is concerned he and his wife will need to sell the farm for whatever they can get and move to a city. Neither Mr. J nor his wife has any easily marketable skills for an urban economy. He has already had to let go of workers who have been laboring on the land beside him for years. Family traditions have been discontinued, as all of his adult children have already gone to the city to find a source of enhanced income, realizing there was no longer a future on the family farm. Mr. J feels lonely and isolated, with a sense of shame and demoralization. He has recently purchased a gun as he does not know if he can continue living this way.

Kazlauskas and Quero identify “AD as one of the most likely causes of consequences of the pandemic on mental health.” Based on early European and American data, as well as the experience of past pandemics, experts anticipate an increase in AD worldwide as a result of risks of contracting and spreading the virus, caring for those who are ill, dealing with multiple episodes of grief, loss of employment and financial security, and social impact of public health restrictions. European studies in the first months of the pandemic have found that both health and work-related stressors constituted risk factors for the development of AD. A web-based survey in Poland conducted in March-April when the country first went into lockdown found that 49% of respondents reported symptoms of AD-related to COVID-19, with women and those without a full-time job being most affected. When the ADNM-20 was administered, 14% of this sample met ICD-11 criteria. British researchers used the Internet to conduct a cross-sectional survey of over 1,200 citizens at two different times in the pandemic, March-April, and June. Probable AD was found in approximately 16% of the respondents with the diagnosis, and the study hypothesis of a dose-response effect was confirmed with those who experienced four or more COVID-19-related stressors being more likely to meet diagnostic criteria. Participants who were younger or in isolation had higher rates of AD. Health care professionals are at particularly high risk of developing AD during the pandemic due to long hours caring for very sick patients often without adequate resources; seeing intense suffering and death; conflicts between professional and personal duties; and fear of contracting the virus and exposing friends and family. Swiss researchers administered the ADNM to practitioners working in a hospital during COVID-19 and diagnosed 8% with AD, with nursing staff and women having higher rates of AD and depression. The authors emphasize this group may benefit from psychotherapeutic techniques that have benefited health care professionals in China, such as cognitive restructuring and efforts to reduce the use of substances as a coping mechanism.

These pervasive negative effects on mental health are likely to endure even once a vaccine becomes available. This, combined with shortages of overstretched mental health professionals, likely results in delayed diagnosis and treatment of AD that may well become chronic.

The magnitude of the impact of COVID-19-related ADs makes it imperative that public mental health organizations and practitioners identify and deploy effective diagnostic and treatment options. The nature of the new ADNM as a self-report measure enables it to be potentially utilized to screen large populations. Prior research with virtual treatment modalities has been promising, and there is an urgent need to expand and implement the use of telehealth and online therapies, especially as outreach to the most vulnerable populations.

One contributor to this discrepant epidemiologic data has been the lack of a structured diagnostic instrument for AD similar to those available for other psychiatric disorders, although a new instrument has been developed. The instrument is a 29-item self-assessment—the DIAD—that has been used in two sample populations of patients already diagnosed with adjustment disorder. The assessment tool identified three major characteristics of patients with AD: intrusive memories of the event, avoidance of feelings, and a failure to adapt. The authors conclude that this tool will likely facilitate future research in the area of ADs. The DIAD covers the domains of stressful life events, onset and duration of the stressor, symptoms of distress, and impairment from the stressor, along with the relationship between these and the stressor. Further studies will, of course, be needed to establish psychometric validity, but the development of the DIAD is certainly a step forward in diagnostic rigor for AD.

ETIOLOGY

Current knowledge regarding the relationship between a stressful life experience and the development of symptoms remains incomplete. Unresolved questions persist in the literature regarding the etiology of AD. Many authors in the field criticize the idea of linking a single stressor to a symptom complex. As discussed earlier, if a stressor does impact an individual, the model of linear causality has less utility than other complex models of causality. Recent literature has considered symptom formation following a stressor from a variety of paradigms. These include psychological models of processing stressful life experiences; psychodynamic models of affect attunement; the impact of early life experiences and ongoing psychiatric issues on the vulnerability to stress; and biologic vulnerability to stressful life experiences.

Israelachvili provides a compelling description from the social psychology literature of processes that may underly the idea of adjustment. He explains that adjustment often results from the experience of transition and that an individual must adapt to that transition. Transitional periods in an individual’s life might be considered an adjustment to a new set of circumstances. He compares this to the more humanistic idea of adjustment in which one might bring their own resources to a situation in the transitional process, to both change the self and perceived circumstances or environment. This is to be distinguished from the process of socialization, where the transition only involves an understanding of a new set of circumstances, such as the culture of a new place of employment or the background of a spouse's heritage. He also underscores our lack of understanding of what constitutes a good adjustment: Describing that adjustment is often considered through the presence of maladaptation to a transition, and it is through these negative markers that we define adjustment.

One investigator describes the integration of stressful life experiences as a series of responses. The first of these involves the realization that a stressful event has occurred. A period in which the information is suppressed then follows. There is then alternating intrusion of the event and attempts at suppressing it, along with working through the information, which results in an integration of the material into one's cognitive schema or in symptom formation.

Another author has elaborated a theory of associative network formation following a significant stressful experience. The network consists of three elements: stimulus information about the stressor; information about cognitive, behavioral, and physiologic reactions to the stressor; and meaning elements representing basic assumptions and their violation. Symptoms occur when one is re-exposed to an element of the associative network. An example the literature offers is how meeting a former employer may trigger thoughts about the unexpected dismissal from current employment and why this happened. Psychotherapy would be aimed at modifying this associative network.

Another model proposes that the etiology of symptoms comes not only from a representation of the event in memory but also from individual differences in the meaning and understanding of the stressor and its sequelae. If the meaning of a stressor to an individual greatly disturbs their autobiographical narrative, it will lead to more disturbing psychological consequences. In such cases, it becomes more difficult to reorganize an understanding of previous experiences to reestablish a stable sense of self.

Contemporary psychodynamic theory focuses on the context in which an event occurs and how this leads to symptom formation. The intersubjective paradigm delineates the critical nature of attunement from others following a significant stressor. A stressor leads to the generation of an affective experience, which in turn leads to the desire for understanding of this affect. If others fail to attune to this affect but rather criticize, reject, or neglect the individual, he is left to cope on his own, leading to symptom formation. Though generally supported, this idea has been questioned in some studies, which infer that excessive social support can, in fact, lead one to feel incapable of coping unaided, in turn leading to lower self-esteem and distress.

Psychodynamic theory also posits that it is the lack of an experience of affect or feelings about the stressor that generates problems. Individuals may not have the opportunity to experience their feelings about an event or toward a person because the emergence of these feelings represented a danger or threat for whatever reason. Perhaps it threatened a caregiver, perhaps there was not sufficient time, or perhaps this was already a learned style. The emergence of these feelings signals danger and a sense of anxiety. Individuals develop psychological defenses to mitigate this anxiety which in themselves can cause problems. For example, anger at an individual may be turned against the self, resulting in symptoms of depression and demoralization.

Some evidence exists that individuals with greater deprivation early in life are at greater risk for developing symptoms following a life stressor. Current literature points to the importance of childhood experiences in the vulnerability to symptom formation in response to later life stress. Evidence from a variety of sources suggests that early experience with diminished control may foster a cognitive style characterized by an increased probability of interpreting or processing subsequent events as out of one’s control. This may represent a psychological vulnerability to the development of anxiety. Research in the area of adverse childhood events further underscores the contribution of early life experiences in the generation of depressive affect later in life. For many, the experience of adversity in childhood is associated with the development of further stressful life events over the course of development and adulthood. Both early adverse childhood events, as well as these associated later adult experiences of adversity, seem to contribute partially and significantly to the development of the experience of the effect of depression.

Recent literature has furthermore examined the question of resilience to stressful life experiences. Most of this research has focused on resilience in the face of adversity during childhood and adolescence. Studies of children exposed to stressors including war, family violence, poverty, and natural disasters have revealed a consistent pattern of individual characteristics associated with successful adaptation. These include good intellectual functioning, effective self-regulation of emotions and attachment behaviors, a positive self-concept, optimism, altruism, a capacity to convert traumatic helplessness into learned helpfulness, and an active coping style in confronting a stressor.

Biologic theorists have postulated the role of numerous neurotransmitters in the generation of pathology in individuals most at risk at the time of a stressful life event. Following a review of eleven neurochemical, neuropeptide, and hormonal systems, one author postulates that changes following acute stressful experiences may lead to long-term risk factors for the future capacity to cope with stress. This “allostatic load” of neurochemical networks may relate to individuals’ resilience in the face of stressful life events. One prediction is that individuals in the highest quartile for measures of HPA axis, corticotrophin-releasing hormone (CRH), locus coeruleus-norepinephrine, dopamine, and estrogen activity, and the lowest quartile for dehydroepiandrosterone (DHEA), neuropeptide Y, galanin, testosterone, 5HT1A receptor, and benzodiazepine receptor function will have the highest index for psychobiological allostatic load and increased risk for psychopathology after exposure to stress. These neurotransmitters act through brain regions, including the amygdala, hippocampus, locus coeruleus, and prefrontal cortex, deemed critical in the modulation of a stressful experience.

There are few actual imaging studies looking at the brain changes associated with AD. However, one imaging study of 25 patients with AD found that patients with AD had decreased gray matter volume in the right medial frontal gyrus compared with healthy controls. This brain region is involved in the extinction of learned fear, and a deficit in this area may result therefore in maladaptive behaviors. It is also associated with the default mode network, which is associated with various psychiatric disorders, including depression. Evidence suggests a role for the default state network in the development of anxiety and depression after a stressful event. The involvement of this brain region suggests problematic emotional regulation following a stressful event.

DIAGNOSIS AND CLINICAL FEATURES

A precipitating experience in the form of a stressful event(s) or life situation is the sine qua non for the diagnosis of AD. It is characterized by the development of emotional or behavioral symptoms in the context of an identified psychosocial stressor(s). The symptoms vary widely in form and severity, and the person may or may not be aware of the stressor as being significant. In contrast to other DSM-5 disorders, the AD criteria have no clear and specific symptom profile that defines the condition.

It is deemed clinically significant if accompanied by marked distress “out of proportion to the severity or intensity of the stressor” or by significant impairment in social and occupational functioning. The challenge for the clinician in these situations is to differentiate a reasonable and expected response to psychosocial stressors from that which might indicate a diagnosis of AD. Thus, a reaction within the normal range of human experience must be included in the differential.

Many individuals who seek psychiatric care following a significant life event may desire help in the form of psychotherapy or psychopharmacology, yet their response may not, in fact, be outside of what would be expected. One author notes that there is no way to categorize “problems of daily living” in the current system, yet, with more reliance on mental health practitioners for a role that may have once belonged to families, community support, and religious affiliations, it is critical to understand that such reactions may not be pathologic.

AD may occur in any age group. Some studies have identified school problems as the most frequent precipitant in adolescents, while marital, financial, and health issues are more common in adults. Several studies have described the presenting features of ADs in clinical samples. Common symptoms of AD identified in a large study of AD included depressed mood, low self-esteem, suicidal behavior, increased motor activity, hypervigilance, impulsivity, and substance use. In most of these samples, depressive symptoms have been the most prominent.

Studies of ADs using structured diagnostic instruments have reported high levels of comorbidity. The degree of comorbidity may be an important determinant of the level of impairment and risk for poorer outcomes n persons with adjustment disorder. In one study of Medicare patients, 54% of patients diagnosed with AD also displayed abnormal illness behavior when using the structured interview for Diagnostic Criteria for Psychosomatic Research (DCPR). Symptoms of illness behavior documented included disease phobia, health anxiety, thanatophobia, nosophobia, and illness denial. One-third also met the criteria for somatization. Demoralization, alexithymia, and unstable mood were diagnosed in nearly 30% of patients.

Several studies have reported a significant association of AD with suicidal ideation that beliefs the general clinical impression that is it a less serious mental health condition. In one study of patients who had attempted self-harm and presented to the emergency room, those with AD had more impulsive acts, were more often associated with alcohol abuse, and attempts at self-harm occurred earlier in the course of the disorder than for those patients with a diagnosis of major depression. A 2019 literature review of AD in emergency departments and medical units found a high prevalence of AD in patients presenting with suicidal ideation and behaviors, with poisoning being the most common method of self-harm. However, there was a lack of high-quality studies indicating the need for more solid research to be conducted in this critical area of consultation psychiatry. These findings underscore the seriousness of AD in a subset of individuals; subthreshold conditions may carry high morbidity, including the risk of self-harm and death.

Subtypes

Historically, six subtypes of ADs have been described based on the predominant symptom presentations. DSM-5 continues the subtypes described in DSM-IV-TR. These do not identify specific symptom profiles for each of the subtypes; however, attempts have been made to more accurately characterize them. Notable symptoms for individual ADs subtypes are (1) depressed mood: depression, hyposomnia, low self-esteem, and suicidal indicators; (2) anxiety: generalized anxiety, increased motor activity, and situational anxiety; (3) disturbance of conduct: impulsivity, lack of insight, and violent behavior; and (4) mixed disturbance of emotions and conduct: excessive alcohol ingestion, suspiciousness, hostility, defrauding behavior, and homicidal ideation. A study in a population of primary care patients found that the anxious subtype was the most prevalent of the ADs, twice as prevalent as the depressive subtype, and far more prevalent than other forms.

There was a movement to include two additional subtypes in DSM-5. The first of these involved abnormal grief, but this was ultimately included in a separate section of the diagnostic manual. The second involved a subtype of PTSD/acute stress disorder. This was to include individuals with symptoms that do not rise to the full diagnostic criteria of either of these disorders but met many of the criteria. Both subtypes underscore the relationship between these diagnoses, as all involve a stressor and ensuing symptomatology. Ultimately, however, the PTSD/ASD subtype was not specifically included in the DSM-5 but was acknowledged through the inclusion of the category of Other Trauma- and Stressor-Related Disorders (Table 25–1).

A 45-year-old nurse Ms. D had been detailed 4 months earlier from her usual primary care assignment to the acute medical unit of an academic medical center to help manage a COVID-19 surge in her state. She presented to the center's emergency department after having ingested 10 tablets of the 5-mg zolpidem tablets her family nurse practitioner prescribed her for occasional insomnia. She has no previous psychiatric history or diagnosis. After taking the medications, she told her wife, who called an ambulance. She felt that the exigencies of the pandemic had constrained her to practice outside her scope yet also felt guilty that she was not more altruistic about being given the opportunity to assist her colleagues and care for very sick patients. Her children, 9 and 14, have been attending school online, and this has resulted in tension between her and her wife about who will monitor their activity. Ms. D is torn between visiting her aged parents and placing them at risk, and worrying about how the effects of prolonged isolation on their chronic health problems. The constant fear of contracting the virus and the even greater anxiety about exposing her wife, who is immunosuppressed, have left her unable to sleep, periodically tearful at work and at home, retreating to her bedroom rather than joining in family meals. She is not sure if she just took the pills because she wanted to not wake up for a while and forget everything or really wanted to die. During the interview, after acute medical stabilization, she was tearful at times and alternated anger at the hospital and her wife with shame about her overdose and the extra stress it placed on her family. Following crises intervention in the emergency setting, she responded well to individual psychotherapy over a 6-month period, as well as a peer-support group of other health care professionals dealing with the strains of the pandemic. The therapist helped Ms. S negotiate an assignment to a new vaccination clinic being set up outpatient, which helped her feel she was making an important contribution to the effort to combat the pandemic in a way that took advantage of her competencies. Ms. S and her wife were able, with the help of a shared therapy session, to develop a schedule for child care responsibilities that reduce the friction in their relationship. Ms. S was started on an antidepressant with the expectation that it could be tapered after 6 to 9 months, depending on the state of the pandemic. When she left the mental health care she had, she was not only in full remission but felt she had developed new resilience in the face of challenges.

Unspecified

DIFFERENTIAL DIAGNOSIS

Stressful life events frequently trigger or exacerbate a wide range of psychiatric disorders. The largest number of studies investigating the differential diagnosis of AD has usually compared the depressed mood subtype to the upper threshold of major depression and the lower threshold of patients without a diagnosable illness according to DSM. This research has supported the middle or transitional position of AD in terms of symptom severity, impairment of function, course of illness, and prognosis. However, the resemblance of patients with AD to “normal” patients raises the interesting question of whether the syndrome is most appropriately understood as a psychiatric illness or as “problems of living” that become overwhelming as a result of an individual’s lack of internal resources and external supports.

The presence of a stressor in the AD diagnostic criteria places acute and post-traumatic stress in the logical differential diagnosis.

The nature of the stressor and the accompanying constellation of affective and autonomic symptoms have been far better defined and characterized for both stress disorders. In contrast, the stressor in AD can be of any severity, with a wide range of possible symptoms. When the response to an extreme stressor does not meet the acute stress or post-traumatic disorder threshold, the AD diagnosis would be appropriate, reinforcing the rationale of placing them under one diagnostic heading.

Some authors have suggested that AD within a stress context may be a *forme fruste* of PTSD for patients lacking either the severity of the stressor or the required number and type of symptoms for post-traumatic diagnosis. Acute stress disorder is even more closely allied to AD in that it also has a limited time course and often a better outcome. Identifying the factors of genetics, environment, or their combination, which account for the different developmental course of stress-related disorders is an area warranting further research. With the placement of the AD in the category of Stress Response Syndromes, this is more likely to happen in future years. The precise nature of the relationship between the stress disorders remains unclear, though there appears to be a correlation between these entities. One recent study of 544 bereaved Israelis identified a close relationship in the new ICD category of prolonged grief disorder (PGD), PTSD, and AD. The severe symptoms of PGD in patients appeared to be mediated both by the severity of the traumatic loss, serious life events, as well as by the concurrent symptoms of PTSD and AD.

The AD subtypes need to be distinguished from subthreshold types of the major mental disorders and the so-called not otherwise specified (NOS). Affective disturbance, anxiety, or conduct problems associated with an identifiable stressor render the diagnosis AD rather than the NOS categories in DSM-V. There is some evidence that these diagnoses do, in fact, represent distinct entities. In one study at the Rhode Island Hospital involving 3,400 patients diagnosed with either depression NOS or AD, important differences were identified. The patients with depressive disorder NOS were more often diagnosed with social phobia and a personality disorder.

The patients with depressive disorder NOS reported more anhedonia, increased appetite, increased sleep, and indecisiveness, whereas the patients with AD reported more weight loss, reduced appetite, and insomnia. There was no significant difference between the groups in the overall level of severity of depression or impaired functioning. The patients with depressive disorder NOS had a nonsignificantly elevated morbid risk of depression in their first-degree relatives. An additional review comparing ADs and depressive episodes in clinical practice focused on the role of personality disorders. Though the rate of personality disorders in patients with ADs is fairly high, the rate in patients with depressive disorders is substantially higher. Interestingly, if the symptoms of AD persist for over 6 months after the stressor or its consequences have resolved, the diagnosis would have to change to the appropriate NOS category, if symptoms remain subthreshold or to a more specific psychiatric diagnosis.

Consultation-liaison psychiatrists have long noted the difficulty of diagnosing a mood disorder in hospitalized or medically ill patients. The differentiation of AD from a mood disorder due to a general medical condition or demoralization is complex. While the medical condition may be the obvious stressor, affective symptoms may arise as a direct physiologic consequence of some medical conditions such as neurologic or rheumatologic conditions or the stress of prolonged hospitalization or disability. In medical and other settings, care must be taken to distinguish between the reasonable and the expected response to psychological stressors, which many authors believe includes demoralization and the inordinate response that may suggest an AD. For the clinician, it may be most useful to see the disorders along a dynamic continuum of affective stress responses where the intensity of distress and nature or degree of functional impairment are more determinative of the need for psychiatric intervention than the actual diagnosis. Normative data on stressor response patterns that differentiate pathologic from abnormal responses are not available in any rigorous fashion, and, as the case below illustrates, clinical and value judgments will continue to play a significant role in the diagnosis of ADs.

A 59-year-old unmarried man has been hospitalized for over 3 months with complications from a perforated gallbladder that required repeated surgeries. He has spent most of the time in the intensive care unit with a nasogastric tube and in severe pain. At times, the surgeons tell the patient that he can recover and return to his job as a security guard while, at other points, the surgical team informs him that the best they can hope for is to discharge the patient to a nursing home. As the patient goes into his fourth month of hospitalization, the nurses notice that for several days a week, the patient is less communicative, seems alternatively sad and then irritable, sometimes refuses to work with physical therapy, and expresses doubts he should ever have agreed to the initial surgery. The surgeon is concerned the patient is “giving up” and requests a psychiatric consultation “for depression and whether the patient would benefit from medication.” After reviewing the chart and interviewing the patient, the resident on the consultation-liaison psychiatry service tells the attending, “I would have bad days too if I had been this sick in the hospital this long.” The attending agrees and informs the surgeons that “the patient’s behaviors are within the normal range of human experience when confronted with protracted serious illness.” The consult team recommends continued clear and consistent communications with the patient about his prognosis and additional support from the patient’s care team, chaplains, and volunteers.

COURSE AND PROGNOSIS

Classic conceptualizations of AD see it as a transitional diagnostic category and thus, by definition, not as an enduring diagnosis: this is one of the reasons clinicians and patients alike have felt it to be less stigmatizing and more hopeful than a major depressive disorder or PTSD diagnoses. The proposed etiology of the disorder assumes that it would not occur without a stressor and that symptoms do not persist beyond 6 months after the stressor or its consequences have terminated. If they do persist, another psychiatric diagnosis would presumably be assigned. The symptoms, therefore, have two prognostic courses: either they resolve or progress to a more serious illness. In some subpopulations, this later course is often the case. In a study by O'Donnell et al., trauma survivors with a diagnosis of AD at 3 months were 2.67 times more likely to go on to receive a more serious diagnosis at 12 months when compared to those without a diagnosis at the 3-month mark. These later diagnoses included PTSD, major depressive disorder, and generalized anxiety disorder. Additionally, over 34% of those in the study continued to meet the criteria for AD at the 1-year time period. This study, among others, challenges the idea of AD as a minor diagnosis, demonstrating that in certain populations, symptoms may well persist or even evolve into a more specific diagnostic entity. An additional study with children and adolescents showed that up to one-third had symptoms of AD which persisted over 6 months, and one-fourth still remained symptomatic after a year. Furthermore, the youth had significant morbidity and poor outcome in contrast to the benign profile of AD found in another research. The majority of studies in diverse settings do support the understanding that AD generally has a shorter duration of illness and hospitalization of patients with AD compared to other Axis I conditions.

Attempts have been made by a number of investigators to address the question of whether an initial episode of adjustment disorder predicts the subsequent development of more specific and severe pathology. Multiple studies have shown a fairly benign course for adults, with a lower likelihood of recovery in adolescents. A 5-year follow-up study at the University of Iowa showed a recovery rate of 71% in adults versus 44% in adolescents. An additional 8% of adults were well at follow-up but had intervening problems, compared to 13% of the adolescent group. Almost 70% of the adolescent group was ill during the 5-year follow period, while less than 30% of the adult group experienced psychiatric disorders in the study period. While most of the adults developed major depressive disorder and alcohol use disorder, the adolescents developed a wider range of major psychiatric disorders, including schizophrenia, bipolar disorder, antisocial personality disorder, substance use disorder, and major depression. The chronicity of symptoms and behavioral disturbance were the best predictor of a poor outcome. The specific adjustment disorder alone did not predict the follow-up diagnosis. In studies following disasters such as Hurricane Katrina in the Gulf, specific factors have been found to decrease the risk of symptoms. These included excellent support systems, high income, and education level, successful mastery of past traumatic events, timely information, availability of recovery services, compassionate understanding from health care providers, and good follow-up.

Research has disclosed a risk for suicide, especially in adolescent patients with AD, not previously fully appreciated. A recent study of 119 patients with AD indicated that 60% had documented suicide attempts in the past, and 96% had been suicidal during their admission to the hospital. Fifty percent had attempted suicide immediately prior to their hospital admission. Comorbid diagnoses of substance use disorder and personality disorder contributed to the suicide risk profile.

Psychological autopsies of 19 adolescent suicides found that one-fifth of the victims had an AD, but over half had a personality disorder as well. The patients who completed suicide were dealing with multiple psychosocial pressures and stressful life events, and few were receiving treatment, suggesting that inadequate coping and lack of professional treatment may have played a role in the deaths. Autopsy results also discovered that the suicidal process was much shorter and more rapid in its evolution in adolescents with AD than in those with other diagnoses and that most of the victims did not have a history of emotional disturbance. Together, these and other studies serve as a cautionary tale to clinicians to reconsider the conceptualization of AD as one of significant suicidal risks deserving of careful monitoring of symptoms and prompt intervention.

A 17-year-old high school senior experienced rejection in his first serious relationship. In the weeks after the end of the relationship, he began to exhibit dysphoric mood accompanied by anxiety and psychomotor agitation. His stress was exacerbated by his inability to play sports and socialize with his friends due to the restrictions of the current COVID-19 pandemic. His parents both had pre-existing medical conditions and did not allow him to socialize with anyone outside of his own family–themselves and his two much younger brothers. He had received counseling in junior high school when his parents considered divorce, and in high school, he began using alcohol and marijuana, contributing to a suspension in his sophomore year for fighting. A month after his breakup, he began to tell his parents that life was no longer worth living without his former girlfriend and that he could not continue with this high degree of social isolation. Two months later, his parents came home from a long walk and found him hanging in the garage with a note stating he could not go on alone.

TREATMENT

The AD diagnosis is common in many specific populations, though given its status as a potential minor and self-limited diagnosis, the clinician is often faced with the question as to whether there is sufficient psychiatric morbidity to warrant treatment intervention. The treatment of individuals with AD requires the careful assessment of the nature and severity of symptoms with consideration of the risk factors associated with poor outcomes, such as poor premorbid functioning and persistent stressors, as well as the risks of treatment, particularly with pharmacotherapy. It is essential to understand the meaning of the stressor(s) to the patient and why it is associated with the presenting symptoms. A paucity of solid formal studies confounds and complicates clinical decision-making. The first formal systematic review of treatment strategies was not published until 2018–this despite its clinical use for decades. This study, however, ranked most all interventions as “low-” or “very low-” quality based on the lack of formal assessment tools for AD, the use of very small sample sizes, the lack of clinician assessments prior to the intervention, the lack of clinician-administered assessments, the lack of follow-up measures, and the lack of control for ongoing medication use.

The primary goals of treatment for AD, as with most mental health conditions, are to relieve symptoms and enable the patient to obtain a level of adaptive functioning that is comparable or, in some situations, better than the level of premorbid functioning. It is important to understand and facilitate those factors that mitigate the pathologic response to stress, as well as taking into account the patient’s level of vulnerability, personal strengths, and history of adaptation to challenges and capacity for resilience. Treatment interventions should be designed to minimize the impact of the stressors on day-to-day function and to mobilize adaptive stress-coping mechanisms.

Specific psychotherapeutic treatment interventions that have been considered in individuals with AD include supportive psychological approaches, behavioral and cognitive-behavioral approaches, problem-solving techniques, relaxation techniques, and psychodynamic interventions. Short-term treatment may be adequate for many patients; however, more extended treatment may be appropriate in situations where individual characteristics predispose the patient to stress intolerance. Depending on the level of acuity and existing supports, crisis intervention and case management may be necessary on a short-term basis to preclude rapid progression, suicide attempts, and perhaps avoid hospitalization. Individual psychotherapy tends to be supportive in nature rather than exploratory, though emerging literature challenges this assumption. It is important to help the patient to better understand the meaning of the stressor and why it may have overwhelmed their coping mechanisms.

A study demonstrated large effect sizes in terms of therapeutic change in a group of patients primarily diagnosed with AD who participated in psychotherapy. Though the proposed mechanism of change involved the development of reliance on more mature defense mechanisms, only a moderate change in defensive functioning was observed. The authors suggested that longer-term psychodynamic psychotherapy or psychoanalysis might be helpful in these responsive patients to further develop a less defensive style. Another study shows promising results for the use of meditation training for patients with both anxious and depressive subtypes of ADs. One group has demonstrated the use of an online virtual reality cognitive–behavioral therapy for use at home as homework assignments for patients with ADs. Interestingly, in a Cochrane meta-analysis, only problem-solving therapies showed a reduction in the time for patients with the diagnosis of AD to return to part- or full-time work. The preliminary findings of internet-based self-help intervention for ICD-11 AD showed promise as well, with a moderate effect size demonstrated for a population of 284 study patients with AD diagnoses using the BADI formal instrument, though the dropout rate in the study was high. Participants in this study reported an experience of an average of four life stressors. Among the most common were too much or not enough work, conflicts in the family, financial difficulties, difficulties due to deadlines, and conflicts at work. Another ongoing study demonstrates the use of multiple modalities tailored for a group of cancer patients. This includes a module of psychoeducation, followed by two modules of group interventions, mindfulness, and eHealth.

In the model, Israelachvili proposed, the therapist might consider the situation of the patient more specifically. If the issue involves a required adaptation, then such models as Acceptance and Commitment Therapy (ACT) or Morita Therapy might be most helpful in adapting to new circumstances. However, in the case of adjusting to new transitional experiences, humanistic client-focused approaches might be most useful. In cases of socialization to new circumstances, either cognitive behavioral therapy or developmental therapies might be more useful, as these promote skills development.

Family, couples, and group therapies may have utility depending on the presenting circumstances. Many individual modalities may well have utility in a group. One study demonstrated good efficacy in the capacity to regulate emotions as a result of group therapy with multiple modalities for women recently diagnosed with breast cancer.

The Dutch have actually developed practice guidelines for managing ADs in occupational and primary health care which aim to reduce suffering, sick leave, disability, and economic losses. The guideline recommendations are based on cognitive–behavioral therapy, stress inoculation training, and graded activity with the goal of improving the problem-solving ability of workers. Recommendations have also been made for the management of patients with AD who are actively deployed. These recommendations can be generally taken as minimizing the stressor, teaching psychological skills, and working with the meaning of the stressor with ongoing suicide risk assessment. Medications should be used for symptoms of insomnia and anxiety in the short run, and antidepressants for more moderate-to-severe forms of depression.

The last 5 years have seen a bit more attention to pharmacotherapy for AD, often with complementary and alternative agents. Although there have been few methodologically sound primary studies, several well-done reviews of the small body of literature on AD psychopharmacology have been published in 2018. Stein’s systematic review of the pharmacology literature could only identify 11 randomized clinical trials. Ironically, one reason for the paucity of rigorous research is the impression that AD is a minor and mental health problem that usually remits without treatment. Thus, pharmacologic decision-making must balance the potential side effects of medications with the considerable symptom burden and risk of suicide that characterize AD. The optimal approach will prioritize patient preferences and medical judgment with contextual features of the specific AD case presentation.

An RCT of the plant extract Euphytose (EUP) involving 182 French outpatients with AD showed a decrease in anxiety for the treatment group. Patients received two tablets of EUP for 28 days. Fifty-seven percent of patients treated with EUP compared to 39%

treated with placebo were considered responders post-treatment with a HAM-A score less than 14. However, the study lacked a specific scale for AD. A randomized placebo-controlled trial of Gingko biloba in patients with generalized anxiety disorder, the anxious subtype of AD, and cognitive decline for 4 weeks found that anxiety, aggression, and global clinical impression scales all showed statistically significant benefits.

A naturalistic study favored antidepressants as first-line pharmacotherapy for AD. Fifty-two adjustment disorder patients treated over 56 days with trazodone (Desyrel) found that nearly 65% obtained remission, and another 26% responded to treatment. The medication was well-tolerated, and its efficacy was due to the amelioration of insomnia, anxiety, and depressed mood. Obviously, the results of these small and early trials require rigorous replication, but they do offer some pharmacologic options to complement the primarily psychosocial treatment of the disorder.

For the anxiety subtype of AD, prospective comparison studies with etifoxine, benzodiazepines, and buspirone have shown the drug is better tolerated and more efficacious than either of the other two agents. Etifoxine is a nonbenzodiazepine drug that modulates GABA-A receptors available in Europe. A 2006 protocol compared lorazepam and etifoxine in 191 patients with DSM-IV AD over 4 weeks. On the Hamilton Anxiety Rating Scale used as the primary outcome measure, etifoxine was not inferior to lorazepam, and the novel agent was better tolerated and had a higher number of responders, as well as fewer patients with rebound anxiety. Another comparator study that used alprazolam had similar results but also found that after medication discontinuation, HAM-A ratings in the etifoxine group continued to decrease while those in the alprazolam group increased and also had more central nervous system adverse events.

There is plenty of less-rigorous evidence from psychosomatic medicine and clinic settings suggesting it is reasonable to consider the judicious use of medications to treat the specific symptoms of ADs. Typically, these are antidepressants and anxiolytics. The growing literature on the adverse effects of benzodiazepines, especially in the older adults and those with a substance use disorder, require reconsidering their use even in consultation-liaison and emergency department settings. Several studies have shown that even short-term use of benzodiazepines for AD can result in withdrawal. It is often helpful and important to treat such issues as insomnia and severe anxiety with pharmacologic interventions in the short run. The treatment of depressive symptoms with pharmacotherapy is less clear. ADs represent the greatest growth area in the prescription of antidepressants, yet the evidence for the utility in improving depressive symptoms in ADs is scant. Selective serotonin reuptake inhibitors have been found to be useful in treating some subthreshold depressive symptoms and may benefit certain subtypes of ADs. It should, however, be emphasized that psychosocial strategies remain the mainstay of treatment, with pharmacologic intervention being a complementary treatment modality. There is a great need for more robust research into the psychopharmacology of AD, with particular attention to the identification of novel neurobiologic strategies. Research that adopts a trauma-stress neuroscience paradigm may prove to be the most promising pathway to identify useful agents for AD.

FUTURE DIRECTIONS

Creating an interactive model that takes into account both stress and resiliency factors that are responsive to individual and cultural differences remains challenging. Questions abound regarding AD. For instance, what is the relationship between AD and other stress-related disorders such as PTSD and acute stress disorder? Are subtypes of ADs more appropriately conceptualized as minor disorders of mood, anxiety, and behavior?

Some authors have suggested a better understanding of the AD might require a radical choice. Either the diagnosis of AD is not based on a definition that lends itself to rigorous investigation—thus, it should be reconsidered—or its pragmatic utility, despite methodologic problems, needs to be recognized as a reason for further research, particularly study of its epidemiologic and therapeutic aspects. The latter option would require continued efforts to improve the specificity, reliability, and validity of the diagnostic category. The placement of the ADs in the Stress Response section of DSM represents the first step in this direction. Further research must also be directed toward developing optimal treatment approaches using randomized controlled trials and rigorous cost-benefit analyses.

The onset of unparalleled planetary crises in the form of climate change, the COVID-19 pandemic, political violence, and widening social injustice will likely result in an increase in AD. Patients, families, communities, and professionals would all benefit from a scholarly strengthening of this clinically valuable diagnostic category so that a more robust understanding of AD may improve prognostication and, most importantly, the discovery of beneficial treatments.

Personality Disorders

C. ROBERT CLONINGER, M.D., PH.D., AND NIGEL LESTER, M.D.

Progress in understanding the psychobiology of human personality has continued during the past 5 years in ways that now reveal its complex multi-component structure, dynamic functioning, and even the evolutionary changes that account for the capacities for self-awareness and intersubjectivity that distinguish modern humans from other animals. Specifically, modern humans have a unique capacity to integrate self-control and self-awareness so that they can self-regulate their habits, emotions, goals, and values coherently, which promotes their health and well-being through self-actualization. Furthermore, the intersubjective awareness of *Homo sapiens* (literally, wise man) allows them to palpably feel their connection with other people and nature, which allows them to distinguish between self and other while consciously identifying with other people and nature. Together these capacities allow a person to develop in their health and well-being by cultivating self-awareness and intersubjectivity with flexibility, creativity, and prosocial values. The genetic basis of the capacity for self-actualization and self-transcendence is not present in the genomes of other hominoids, such as chimpanzees or Neanderthals, even though we share nearly all the same protein-coding genes with them.

The genetic basis for modern human awareness depends on RNA genes that regulate the expression of protein-coding genes in three distinct systems of learning and memory: habits, intentionality, and self-awareness. Nearly all the heritability of human personality is explained by 972 genes, which are organized in these three nearly disjoint networks. A comparison of the genomes of modern humans, Neanderthals, and chimpanzees revealed that 267 genes of these genes for personality are found only in *Homo sapiens.* Most of the genes found only in modern humans are active in the self-awareness network and under positive selection. Ninety-five percent of these 267 genes were RNA regulatory genes, mostly long RNA genes that do not code for proteins, and that, instead regulate the expression of protein-coding genes. The RNA regulatory genes also organize the co-expression of other genes in functional clusters, including their overexpression in brain regions that specify the components of the brain network for self-awareness previously identified by functional brain imaging.

The three genotypic systems for human personality evolved in a staggered manner. The most primitive arose in monkeys and apes about 40 million years ago and is responsible for emotional reactivity; that is, it regulates impulses, learning habits, social attachment, and conflict resolution. Less than 2 million years ago, the second network emerged in a common ancestor of Neanderthals and modern humans, enabling the regulation of intentional self-control, that is, self-direction and cooperation for mutual benefit. Finally, about 100,000 years ago, the network of creative self-awareness emerged in behaviorally modern humans with a capacity for narrative art, science, and spirituality.

These new findings uncover the basic mechanisms required for promoting healthy personality development and, remarkably, physical, mental, and social well-being. It turns out that a healthy personality is actually the foundation for all aspects of well-being in general because it provides the regulatory processes by which we learn to integrate our habits, goals, and values so that they are congruent, reasonable, and beneficial for ourselves, others, and the world in which we live. The authors will briefly summarize a few major findings in order to orient readers before going into more depth about personality and its disorders. In this way, readers can update what they already know or assume to be true with new knowledge that will provide a more comprehensive and empirically sound approach to the assessment and treatment of personality disorder (PD).

THREE INTERACTIVE SYSTEMS OF LEARNING AND ADAPTABILITY

In addition to general intelligence, modern humans have three distinct systems of learning: behavioral conditioning, intentionality, and self-awareness. These are partially dissociable but normally interact to allow people to adapt to changing internal and external conditions in ways that are realistic and health-promoting. Integration of these three systems is essential for the development of human personality and for human health and well-being.

Consequently, the strengths of earlier theories and treatment methods that address only one or two of these three learning processes can now be incorporated into a more comprehensive biopsychosocial paradigm, thereby enabling more consistent and complete benefits for a broader range of people. Our new knowledge provides a solid foundation from which to deepen our understanding of the mechanisms of development and change that are needed for an effective and positive way to promote well-being and treat PDs in ways that are appropriate for the challenges of modern times rather than just managing them interminably.

FLUIDITY AND CREATIVITY IN THE DYNAMICS OF PERSONALITY DEVELOPMENT

The underlying mechanisms of human personality are systems of learning, so personality is not fixed or determined at birth. When we are healthy, we are constantly learning and creating our health in each moment. This fluidity and creativity allow us to both shape and adapt to changing internal and external conditions. The emergence of self-awareness in modern humans brought with it cognitive skills for vivid recollection of the past, assessment of the present, and imaginative anticipation of alternative futures. Self-awareness also provides humans with the capacity to develop social norms and cultural values to maintain large communities in which people can normally cooperate respectfully with one another and, optimally, identify with one another and the world with a harmonizing sense of interdependence and intersubjective awareness. For example, shared reciprocal interactions between a caretaker and child allow each to experience their having an impact on the experiences of the other. Through such intersubjective relationships, children develop trust and self-respect when they feel loved and loveable, valued and valuable. Unfortunately, some conditions (e.g., abuse and neglect of children, and, more generally, fear, violence, and social injustice in society) impair the development of self-awareness, impairing progress in self-actualization, intersubjectivity, and self-transcendence. As a consequence of such impairments, both individual and cultural perspectives about the goals and values that guide the way people live can become maladaptive and unsustainable. Fortunately, adolescence brings with it changes in personality that stimulates reassessment of cultural traditions, thereby facilitating a creative process of identity formation and re-evaluation of a society’s goals and values that may no longer be sustainable or beneficial.

For example, the World Values Survey and other prospective studies have identified three clusters of people whose values correspond to the dominance of one of the three systems of human learning: (i) “traditionals” who learn mostly by behavioral conditioning and are highly emotionally reactive and resistant to changing their habits and customs, (ii) “materialists” who rely mainly on self-control and are highly self-interested but may cooperate for mutual benefit, and (iii) “cultural creatives” who are highly aware of themselves and their connections with other people and nature so that they are highly egalitarian, self-transcendent, and altruistic. Younger birth cohorts are shifting toward a majority being “cultural creatives” so that they are much more egalitarian, less materialistic, and more self-transcendent than their predecessors. Cultural creatives are more socially and ecologically aware, and so they are concerned about climate change, excessive militarism, and the focus on competition and profit that leads to social inequity and frequent ill health in developed countries, including mental distress and PD in addition to chronic physical diseases. To the detriment of individual and collective well-being, such shifts in paradigm are often opposed by older adult authorities in order to conserve their traditions and authority by delaying changes that the more self-transcendent members of society perceive to be needed for a healthier and sustainable society. For example, in materialistic societies, the expression of self-transcendence is suppressed by social norms during young adulthood, but this is not sustainable as people inevitably must face ultimate situations that they cannot control, such as unpredictable climatic change, suffering, and death. Empirically, self-transcendence is a crucial component of people's ability to live in harmony with one another and the natural world.

IMPORTANCE OF SELF-TRANSCENDENCE FOR PERSONALITY DEVELOPMENT AND HEALTH PROMOTION

People and their cultures have a high frequency of personality dysfunction and related impairment in physical, mental, and social well-being unless they have clear insight and understanding of how humans can integrate their three systems of learning and memory. In brief, the path to well-being is a path of increasing awareness involving increasing character strengths for Self-directedness (i.e., intrapersonal character strengths, such as being resourceful and responsible), Cooperativeness (i.e., interpersonal character strengths, such as being tolerant and helpful), and Self-transcendence (i.e., transpersonal character strengths, such as being altruistic and contemplative), which guide and direct the regulation of emotional desires and attachments, prioritize goals and brings habits and goals in congruence with values. These three strengths of character create a dynamic cycle in which self-transcendent values inspire creative thinking, and plasticity allows its free expression. The same process produces personal well-being through self-actualization and collective well-being through intersubjective (transpersonal) identification with others and the natural world. Empirically, in prospective studies, the initial personality characteristic that leads to the most growth and maturation in personality is high Self-transcendence, but there are substantial additional contributions from high Persistence and Novelty Seeking. Self-Transcendence and Persistence are also positively correlated with nearly all character strengths and virtues. Large-scale randomized controlled trials show significant benefits from activities that promote the development of each of the three dimensions of character, as well as substantial synergistic effects from their joint activation that help to moderate emotional distress.

There is much that we can learn from the strengths and limitations of earlier theories and treatment methods for cultivating Self-directedness and Cooperativeness, which have long been recognized as important contributors to character and health. However, nearly all prior models of human personality have been materialistic (e.g., behaviorist, somatic, and pharmacologic approaches) or dualistic (mind–body approaches assuming that people are separate from one another and the rest of nature). As a result, prior models, including DSM-5 and ICD-11, have inadequately recognized the importance of the fact that high Self-transcendence is the major predictor of healthy personality development, as is true even in highly materialistic societies because it is a fundamental characteristic of human nature.

Self-transcendence is the process by which a person becomes aware of their participation in something greater than their individual self. The palpably felt experience of identification with someone or something greater than the individual self can transform a person's perspective incrementally from a sense of separation to intersubjectivity and eventually to participate in the unity of all beings. More specifically, the conscious realization of participation in something beyond yourself, such as union with humanity, nature, or God, evokes positive emotions, particularly joy and awe, which are often combined with attitudes of humility and reverence. Prospective studies indicate that the cultivation of self-transcendence and well-being involves the dynamic interplay of three processes: the awakening of plasticity (i.e., being able and willing to change), virtue (i.e., having intuitive insight into what is good for a person's self and others), and creative functioning (i.e., being innovative, purposeful and responsible so that our habits are congruent with our goals and values).

The cultivation of self-transcendence by these three processes describes the essential features of healthy personality development, which leads to a life that is healthy, happy, and good. Even when a role for self-transcendence in developing a healthy personality has been partially recognized, emphasis was initially placed on the conditioning of habits by behaviorists, or intellectual analysis of dysfunctional thoughts and emotions by cognitive therapists, or struggle with unconscious irrational forces by psychoanalysts. There was little consideration of the need to awaken a more self-transcendent perspective until the development of "third-wave" psychotherapies and positive approaches to psychiatry and psychology. The addition of tools for cultivating self-transcendence through meditative practices, nature experiences, and virtuous acts have reduced drop-out from cognitive-behavioral and psychodynamic therapies and improved outcomes.

It is to be expected that people reared in materialistic cultures are likely to be resistant to the evidence that self-transcendence is essential for healthy living. Nevertheless, most people feel empty and discontented until they directly experience the interdependence of all things as a result of the intrinsic human need for self-transcendence. The interconnectedness and inseparability of living things is not simply a matter of opinion or belief. An increasingly large body of evidence from research in biology and ecologic systems has shown that symbiosis and cooperation are more involved in the healthy functioning of ecosystems than the competition. Research on the microbiome in humans and in soils has proven that the deep interconnections within the biosphere are necessary for the body and communities of organisms to function properly. These interactions with the microbiome function at the level of genes and epigenetics, and the microbiome seems capable of interacting with the human nervous system and endocrine system. The cells of living organisms are only partially separated from one another and the world by the semi-permeable boundaries of cells that are actively engaged in the exchange of materials in and out of themselves. More deeply, according to quantum physics, quanta are constantly arising from, and returning to, a universal field of energy and information, which is called the Higgs field.

Human experiences of transcendence also speak to the interconnectedness of living things. It is natural for people to feel their connection with other people and the world. Individuals who have had transcendent experiences, including many physicists, biologists, and cognitive scientists, frequently regard the belief that we are separate from other aspects of the world as illusory. They would argue that this illusion is caused by self-preoccupation and inadequate development of an allocentric or transpersonal perspective, as is seen in various forms of psychopathology, such as autism or antisocial PD. In reality, they suggest that all living organisms are actively engaged in relationships with their surrounding world in which we are embodied, embedded, enactive, and extended. According to Albert Einstein, for example,

> “A human being is a part of the whole, called by us “Universe,” a part limited in time and space. He experiences himself, his thoughts and feelings as something separated from the rest – a kind of optical delusion of his consciousness. This delusion is a kind of prison for us, restricting us to our personal desires and to affection for a few persons nearest to us. Our task must be to free ourselves from this prison by widening our circle of compassion to embrace all living creatures and the whole of nature in its beauty.” (Einstein A. Letter to Norman Salit. March 4, 1956. Princeton University Press.)

In fact, more than three out of every four persons experience moments of self-transcendence at least occasionally. The capacity for adopting allocentric and transpersonal perspectives develops in human children around age 7 with subsequent development of ethical values and virtues such as kindness and fairness, which are based on awareness of connections beyond our individual self. In materialistic societies, however, the level of self-transcendent traits decreases during early adulthood when people are encouraged to focus on work and marriage, and then rises again as people must face ultimate situations that they cannot control. Prospective studies indicate that the proportion of people who are highly self-transcendent (variously described as post-materialists, cultural creatives, or creative characters) is increasing from approximately one-third in older birth cohorts to nearly half of younger birth cohorts of the general population, with higher rates in egalitarian countries and lower rates where self-interested materialists dominate social institutions and limit freedom of expression.

Despite how common intersubjective and self-transcendent experiences are in the general population, the scientific investigation of these human phenomena has always been controversial outside of domains like Anthropology and Religious Studies. Scientists and philosophers who identify as agnostic or atheist often consider self-transcendence as an outdated perspective from a bygone era or a relic of our evolutionary history related to the human brain meaning-making functions looking for meaning where there is none (see, e.g., Richard Dawkins, Daniel Dennett). However, all individuals experience some type of intersubjective and transcendent experience, even if that experience is not related to the divine. Many quotidian experiences like ethics, art, culture, beauty, nature experiences, and the search for truth and social justice are experiences of intersubjective and self-transcendent nature. Consequently, it is self-defeating to ignore them when considering improvements in child development, education, health promotion, or therapeutics at any age. Research has demonstrated that nature experiences lead to strong feelings of joy and connection and improve physical and mental health. Similar to nature experiences, experiences of mindfulness are being used the world over to help people experience a bit of peace and self-transcendence in the workday or in our daily lives during stress or isolation, which was prevalent during the coronavirus pandemic.

These studies and experiences suggest that we are not only healthiest but also most realistic when we are aware of our extended relationships and act in ways that reflect the deeper reality of our interconnectedness with all things. It is illusory to regard other people and nature as mere objects from which we are separate. In reality, we are interconnected aspects of a greater whole, and we harm and disturb ourselves when we abuse or neglect others. Given the contemporary threats to human survival from our disharmony with one another and the planet that we share, the time has come for psychiatry to contribute all that it can to promote the development of healthy personalities and the transformation of the resources and values of our cultural institutions that are needed to provide the milieu to support healthy personality development.

Why Has the Importance of Self-Transcendence Been Neglected So Often?

In view of the vast evidence for the importance of Self-transcendence for healthy personality development and for well-being generally, it is useful to consider why its role has been neglected so often during the past century. The importance of self-awareness, and particularly self-transcendence, is actually prominent in wisdom literature that extends back to the earliest descriptions of the path to well-being in antiquity by Homer, Plato, and other positive philosophers, as summarized by Cloninger (2004). Even at the beginning of the 20th century, there was substantial scientific and popular interest in investigating intersubjective and self-transcendent phenomena, such as the benefits of virtue or the possibility of extrasensory perception, that could not be explained by materialistic or nominalist theories of reality. However, fraud was detected often enough that most scientists became reluctant to attempt rigorous research to test the assumptions of local realism until the emergence of theories of relativity and quantum mechanics in physics.

Likewise, psychology and psychiatry were handicapped by the absence of techniques to uncover the underlying processes of motivation and learning in humans empirically until the tools of functional brain imaging and genetics were developed. Much research in psychophysiology was conducted on experimental animals who do not possess human self-awareness. Psychiatrists, such as Freud, recognized the inadequacy of tools for psychobiological research but speculated about the underlying structure of human motivation and learning using imagination and astute observations of their patients. Of course, their speculations were biased by their own uncertain assumptions about the nature of reality.

The recent identification of the genetic and neural basis for the three complex systems of learning and memory in humans reveals that the clinical assessment of Self-transcendence is also vulnerable to a serious error that had been made by early personality psychologists and that persists in the minds of most of their successors to this day. For many decades most psychologists have assumed that personality is best measured in terms of quantitative dimensions, such as Eysenck’s measures of Neuroticism, Extraversion, and Psychoticism. They also assumed that the genetics of apparently uncorrelated dimensions could be studied independently of one another. However, these dimensions (“factors”) were artificially created by the uncertain assumptions of restrictive statistical models, including that the factors they extracted were homogeneous and largely independent. During the last few years, the authors were surprised to observe that the genetic basis for personality was related to configurations of multiple personality traits rather than to the individual traits (such as Self-directedness) that emerge in particular person–situation interactions as a result of heterogeneous processes in different people. Put another way, the natural measurement units for the genetics of personality are multi-trait configurations, not individual dimensions. Dimensions, such as Self-directedness, Cooperativeness, and Self-transcendence, are useful to measure because they describe person–situation interactions, but they are actually composite effects of multiple underlying adaptive networks specified by different genes and brain circuitry in different people. There are many molecular and brain pathways to behaviors that look similar superficially or that overlap partially.

The assessment of human character traits illustrates the difficulty of understanding human personality structure and development prior to the availability of modern methods for genotyping, brain imaging, and unrestricted analysis of complex adaptive systems using artificial intelligence. For example, using these modern methods, a multidisciplinary team of experts led by Igor Zwir and Robert Cloninger (2018–2021) identified five clusters of people with different genotypic profiles who differed in Self-transcendence and other character traits. People with a genotypic predisposition for creative self-awareness were high in Self-transcendence accompanied by high Cooperativeness and Self-directedness; they were often idealistic, altruistic, and contemplative with frequent self-transcendent experiences. People with the genotypic network for intentional self-control were low in Self-transcendence and highly developed in both Self-directedness and Cooperativeness; they were often materialistic and individualistic and would do things for mutual benefit, but they would not make sacrifices for others. Other clusters with different genotypic backgrounds were low in Self-directedness and/or Cooperativeness, even though some of these reported that they were high in Self-transcendence. These latter individuals had PD with schizotypical features and were highly emotionally reactive and cognitively disorganized despite reporting that they were high in Self-transcendence. In other words, people who report that they are high in Self-transcendence may be either highly self-aware (i.e., high in all three character traits), or they may have magical thinking and perceptual aberrations and not be truly self-transcendent, as is seen in schizotypy. This heterogeneity became clear once multi-trait profiles were studied and was confirmed once the different molecular and brain mechanisms could be measured. Until this heterogeneity was uncovered, however, many clinicians, unfortunately, neglected to distinguish between individuals who were highly self-aware and those with magical thinking. Studies that used the individual measure of high Self-transcendence to predict well-being found highly variable outcomes, which some falsely concluded implied that self-transcendence was not a beneficial trait. Today, we are fortunate that modern tools have allowed us to show that the creative profile (i.e., high scores on all three character traits) is a strong and consistent predictor of physical, mental, and social well-being. In other words, self-awareness leads to all three character traits being well-developed, so a person cannot be truly self-transcendent unless they are also self-directed and cooperative. Likewise, a person cannot be fully hopeful and self-actualizing (spiritual aspects of self-directedness) or loving and compassionate (spiritual aspects of Cooperativeness) unless they are truly self-transcendent.

GENERAL IMPORTANCE OF PERSONALITY ASSESSMENT IN MEDICINE

The understanding of personality and its disorders is what has most often distinguished psychiatry fundamentally from other branches of medicine. A person is a self-aware human being, not a machine-like object that lacks self-awareness. Personality refers to all the characteristics that distinguish a constantly developing, self-organizing human being from a predictable machine-like object. In other words, personality refers to all the ways by which someone shapes and adapts in a unique way to an ever-changing internal and external environment.

Diverse therapeutic techniques, such as diet, exercise, mood self-regulation, meditation, or acts of kindness, influence health, and personality development in ways that are largely indistinguishable from one another or from effective allopathic treatments. Hence, according to the principles of person-centered therapeutics described by the Cloningers, the development of well-being appears to be the result of activating a synergistic set of mechanisms of well-being, which are expressed as greater functioning, plasticity, and virtue in adapting to life's challenges. The conditions that promote well-being and recovery from illness involve a set of common features of health that include hope, empathy, and respect for both self and others. These common characteristics of well-being emerge from a self-transcendent outlook on life, which is typical of healthy and creative people in all human cultures. An outlook of separation predisposes a person to feelings of fear, alienation, and individual pride or shame, thereby predisposing them to ill health and dissatisfaction with life. Person-centered care promotes health by providing the experience of an outlook of unity in the therapeutic alliance, which can later be generalized beyond the alliance. An outlook of unity fosters well-being by activation of a synergistic spiral of increasing self-directedness, cooperativeness, and self-transcendence, as will be described in more detail later.

Only about 15% of the variance in treatment outcomes is attributable to specific techniques of different psychotherapeutic schools, whereas about 85% of the variance in psychotherapy outcomes is explained by common factors shared by different approaches. What is attributed to the strong placebo effects observed in most drug or psychotherapy trials is substantially determined by common psychosocial factors, which can be as large or larger than putatively specific treatments. The common factors in all treatments include the patient's characteristics, the therapist's qualities of respect (i.e., prizing, unconditional positive regard, acceptance, trust), empathic understanding, and genuineness (i.e., realness, authenticity), and the quality of the therapeutic alliance between them (shared goals, emotional engagement, and exchange). In other words, the common factors for promoting well-being by positive personality development depends on promoting self-transcendence in a human relationship or therapeutic alliance that is intersubjective and coactive. These common factors are characteristic of all truly healthy human relationships, and they are important for the maintenance and recovery of all aspects of well-being, whether physical, mental, social, or spiritual.

Knowledge of the personalities of people provides the biopsychosocial context in which their behavior and relationships can be adequately understood as a complex adaptive process, which is crucial for all diagnosis and treatment. As a result, no psychiatric assessment is adequate without a description of the patient's personality and its development across the lifespan. In fact, it can be argued that person-centered approaches are preferred in all branches of medicine because the neglect of thorough personality assessment and its implications for health leads to people developing many chronic diseases, which are the source of most of the burden of disease in affluent societies. More than 70% of the burden of disease overall could be prevented by universal health care guided by person-centered principles in the individual care and public health and, in particular, effective personality assessment and treatment.

Even if a psychiatrist takes a reductive, rather than an integrative, view of psychological medicine, the assessment of PD is still essential in clinical practice because PD is such a common condition in contemporary society. PD occurs in 10% to 20% of the general population and in about half of psychiatric inpatients or outpatients. People with PD have chronic impairments in their ability to work and love, tend to be less educated, drug dependent, single, unemployed, and have marital difficulties. They consume a large portion of community services, social welfare benefits, public health, and prison resources.

Assessment and Treatment in Clinical Practice

Despite the great importance of personality and its disorders, clinicians seldom have the time or inclination to ask all the questions specified in the DSM-5 criteria for PD. Most psychiatrists find the official criteria of little utility except for rare and extreme prototypic cases. Official criteria have failed to provide the practicing clinician a tool to address personality assessment in an efficient and systematic way that is needed for optimal patient care.

The limitations of DSM for assessing PD are largely the result of its reliance on categorical criteria despite the absence of evidence that PD is composed of discrete entities. Also, most dimensional systems for personality describe the differences between people rather than the intrapsychic processes by which an individual can grow and develop in mental health. As a result, most categorical and dimensional systems for personality have become stigmatizing and are not useful prescriptions for positive personality development. Persons with PD are frequently labeled as "aggravating," "demanding," or "parasitic" and are generally considered to have a poor prognosis for emotional growth and maturation. Alternatively, they may be seductive or dependent and elicit inappropriate blurring of professional boundaries, such as sexual interest or the urge to rescue. These patients challenge the limits of physicians' theoretical knowledge, clinical skills, and even personal maturity. In general, practitioners with low narcissism and high levels of energy, tolerance, flexibility, creativity, and compassion are optimal for treating patients with PD because their own self-actualization allows them to maintain an encouraging and resilient working alliance without the patient dropping out or the practitioner burning out. Recognizing and treating disorders of personality helps clinicians to develop their personal maturity and clinical skills.

Fortunately, it is now possible to carry out a brief assessment of personality and its disorders as part of routine psychiatric examinations in an efficient way that may actually make assessments of both personality and other psychopathology more reliable and valid by identifying risk and protective factors for psychopathology. Such assessments also serve to establish a therapeutic alliance because trust can only be established by intersubjective interactions. Everyone likes to feel that they are appreciated and understood as a person who is respected and valued, not a separate object or diagnostic case. People feel appreciated when a clinician can predict their motivation and behavior with understanding and accuracy. Therefore, the next part of this chapter discusses some basic definitions and then provides the essentials for clinical assessment of personality as an integrated part of the mental status and psychiatric history. Later sections expand upon the essentials to provide a fuller understanding of disorders of personality and their measurement, etiology, development, and treatment.

BASIC DEFINITIONS AND TERMINOLOGY

The terms personality, temperament, motivation, character, and psyche are often used interchangeably. This is both misleading and unjustified. In what follows, these concepts are reviewed to distinguish them with more clarity.

Personality

Personality is both complex and unique: on the one hand, people differ greatly from one another in multiple components of behavior, and, on the other hand, each person expresses only one of their many potential lifestyles. The common characteristic of all existing definitions of personality is that they are functional. That is, they focus on questions related to motivation and the mental adaptation of the organism. Specifically, Allport defined personality as the “dynamic organization within the individual of those psychophysical systems that determine his/her unique adjustment to his/her environment.”

Allport elaborated on this definition by explaining that the expression “dynamic organization” emphasizes that personality is an organized system (“unitas multiplex”) that is constantly evolving and changing. The phrase “within the individual” means that personality refers to intrapsychic processes, not judgmental comparisons of one person to another. The term “psychophysical” means that personality is neither exclusively mental nor exclusively neural but a combination of the two. The expression “unique adjustment to the environment” has both functional and evolutionary significance pointing to personality as a mode of survival and, more generally, learning and adaptation, which is unique to each individual. Allport's use of the verb "determine" suggests that personality traits are determining dispositions that limit a person's behavioral repertoire.

It is now known that people are self-aware and have enough freedom of will to change their behavior in directions that are not necessarily predictable or determined by their past or genetic predisposition. Even monozygotic twins change the way their genes are expressed over the course of their lifetime as a result of epigenetic processes. Human self-awareness permits plasticity in the genome, the brain, and other organs to be shaped by the deliberate choices we make about diet, activity, social relationships, and other intentional, intersubjective, and creative activities. Accordingly, Allport's definition has been modified as follows: human personality is *the dynamic organization of the biopsychosocial systems by which a person shapes and adapts in a unique way to a changing internal and external environment.* In other words, personality is a way of describing the dynamic processes that occur within the person to shape and adapt to life experiences by self-aware learning and proactive planning. The maturation and integration of human personality involves one's growing self-awareness through experiences across a wide range of situations.

It has been widely accepted that personality develops through the interaction of hereditary dispositions and environmental influences. Waddington's notion of genetic canalization (or "epigenetic landscape") has been revised to include reciprocal interactions among genetic endowment, environmental stimulation, and changes in self-awareness across the lifespan. Genetic differences account for about half of the variance in differences between people for most normally distributed temperament traits. The remaining 50% of the variance in differences between people is attributed to environmental influences. Most of the environmental influences are unique to each individual, particularly for temperament traits, but parental rearing and sociocultural norms have a substantial influence on a person's character development. Of note, adoption studies suggest a somewhat lower heritability of about 30% for personality traits. The higher heritability estimates from twins are the result of nonadditive genetic influences (e.g., higher-order interaction among alleles at each locus or among loci), which is the same for monozygotic twins but contributes little to the resemblance of other relatives. Epistasis (i.e., interactions among multiple gene loci) is so strong for both temperament and character that it was difficult to identify specific genes for personality until methods were developed to take epistasis into account.

However, heritability estimates refer only to genetic influences on the differences between people at one point in time. People are able to change from one time to another as a result of growth in self-awareness in ways that are only partially constrained by their past genetic expression. For example, the intelligence quotient (IQ) is highly heritable, but there has been an increase of about 3.3 IQ points per decade that requires frequent restandardization of IQ tests. The increase in IQ scores in successive birth cohorts is called the “Flynn effect.” The increase in IQ is attributable to skill in problem solving on the spot (“fluid intelligence”), such as recognition of similarities, rather than skills dependent on past individual education, such as vocabulary size (“crystallized intelligence”). Likewise, the differences between people in Self-Transcendence at one point in time is 49% heritable, but the prevalence of self-transcendent experiences increased from 48% in 1987 to 76% in 2000 in English people according to studies of the zoologist David Hay. These rapid changes in fluid intelligence and self-transcendence cannot be explained by genetic evolution. Character and fluid intelligence can develop rapidly within individuals in response to cultural developments that influence human society as a whole and/or in response to changes in self-awareness.

From the structural standpoint, personality can be decomposed into temperament, character, and psyche. Roughly speaking, temperament involves basic emotions, character involves rational concepts and propositions of a person and their relationships, and the psyche involves intuitive self-awareness and fluid intelligence. Identity formation is the process of growing in self-awareness of all aspects of being, as discussed later. Self-awareness and fluid intelligence influence personality development substantially, so measures of temperament and character provide an incomplete understanding of personality development unless the distinctive role of self-transcendence as a process and value that motivates growth and self-actualization is recognized. The basic functions of personality are to feel, think, and perceive and to incorporate these into purposeful behaviors that flexibly and creatively express our identity under changing conditions.

Temperament

Temperament refers to the body’s biases in the modulation of conditioned behavioral responses to prescriptive physical stimuli. Cloninger and colleagues (2019) define a person’s temperament as their disposition to learn how to behave, react emotionally, and form attachments automatically by associative conditioning. This definition provides necessary and sufficient criteria to distinguish temperament from other aspects of personality that become integrated with it across the lifespan. Recent genetic work has found over 700 genes that account for nearly all the heritability of human temperament and has confirmed that they are consistently enriched in pathways activated by behavioral conditioning in animals. These pathways include the two major molecular pathways for response to extracellular stimuli, the Ras-MEK-ERK, and the PI3K-AKT-mTOR cascades. These pathways are activated by a wide variety of physiologic and psychosocial stimuli that vary in positive and negative valence and in consequences for health and survival. Changes in these pathways are orchestrated to maintain cellular homeostasis despite changing conditions by modulating temperament and its circadian and seasonal rhythms.

Behavioral conditioning (i.e., procedural learning) involves presemantic sensations that elicit basic emotions, such as fear or anger, independent of conscious recognition, descriptive observation, reflection, or reasoning. Pioneering work by A. Thomas and S. Chess conceptualized temperament as the stylistic component (HOW) of behavior, as differentiated from motivation (WHY) and content (WHAT) of behavior. Modern concepts of temperament, however, emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified and subjected to extensive neurobiologic, psychosocial, and clinical investigation in humans and other animals: Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence. It is remarkable that this four-factor model of temperament is roughly similar to the ancient four temperaments: individuals differ in the degree to which they are melancholic (Harm Avoidance), choleric (Novelty Seeking), sanguine (Reward Dependence), and phlegmatic (Persistence). However, the four temperaments are now understood to be quantitative traits that occur in all possible combinations within the same individual rather than as mutually exclusive categories.

Psychobiology of Temperament. Temperament traits of Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence are defined as heritable differences underlying one's automatic response to danger, novelty, social approval, and intermittent reward, respectively. These four temperament traits are closely associated with the four basic emotions of fear (Harm Avoidance), anger (Novelty Seeking), attachment (Reward Dependence), and ambition (Persistence).

Individual differences in temperament and basic emotions modify the processing of sensory information and shape early learning characteristics, especially associative conditioning of unconscious behavior responses and preattentive components of perception. Temperament is conceptualized as heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavioral traits and habits observable early in life and relatively stable over one's lifespan.

Each of the four major dimensions is a normally distributed quantitative trait, moderately heritable, observable early in childhood, relatively stable in time, and moderately predictive of adolescent and adult behavior. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at age 10 to 11 years were moderately predictive of personality traits at ages 15, 18, and 27 years in a large sample of Swedish children. Whereas character traits develop in a specific direction toward socially favored cultural norms, the number of people who increase in Harm Avoidance, Reward Dependence, and Persistence is about the same as the number who decrease, so that the average of these traits remains the same from ages 20 to 45 years. Novelty Seeking decreases about 10% per decade as a person's impulse control matures.

Table 26–1.
Descriptors of Individuals Who Score High and Low on the Four Temperament Dimensions

Temperament Dimension	Descriptors of Extreme Variants	
	High	**Low**
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Deliberate
	Extravagant	Thrifty
	Disorderly	Orderly
Reward dependence	Sentimental	Detached
	Open	Aloof
	Warm	Cold
	Affectionate	Independent
Persistence	Industrious	Lazy
	Determined	Spoiled
	Ambitious	Underachiever
	Perfectionist	Pragmatist

The four dimensions have been repeatedly shown to be universal across different cultures, ethnic groups, and political systems on every inhabited continent. In summary, these aspects of personality are called temperament because they are heritable, manifest early in life, are developmentally stable, and are consistent in different cultures. Temperament traits are like crystallized intelligence in that they do not show the rapid changes within increasing age or across birth cohorts that are observed for fluid intelligence and character traits. Table 26–1 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages, so neither high nor low scores inherently mean better adaptation.

The component traits ("facets") for each of the four temperament dimensions have distinct learning characteristics and correlate more strongly with one another than with other components of temperament. They share a common source of covariation that is strong and invariant regardless of changes in the environment and past experience. Each of the four temperament dimensions has unique genetic determinants according to family and twin studies, as well as studies of genetic associations with specific DNA markers. However, genome-wide association studies have uncovered groups of genes underlying configurations of multiple temperament traits corresponding to those described in children by Chess and Thomas: (i) "easy" children who have "reliable" temperament profiles with low Harm Avoidance, low Novelty Seeking, high Reward Dependence, and high Persistence, (ii) "difficult" children who have a "sensitive temperament profile" with high Harm Avoidance, Novelty Seeking, and Reward Dependence, and "slow to warm up" who have an "antisocial temperament profile" with high Novelty Seeking, low Reward Dependence, and low Persistence. Despite the value of multi-trait profiles, most research and clinical work has preferred to use quantitative dimensional measures for the assessment of brain mechanisms in research and for clinical assessment and treatment. In practice, configurations can be derived from profiles of their individual constituents, and both approaches have utility.

The four dimensions of human temperament correspond closely to those observed in other mammals. Multiple levels in the phylogeny of learning abilities in animals, from invertebrates to man, indicate that learning has multiple component processes that are hierarchically organized and interact extensively throughout development (Fig. 26–1).

In Figure 26–1, temperament corresponds to the processes of sensation, association, and motivation that underlie the integration of skills and habits based on emotion. Figure 26–1 is useful to specify the hierarchical phylogenetic and ontogenetic organization of learning and its relevance to the concepts of temperament and character, not to compare learning in humans at a particular age to learning in lower animals. Specifically, temperament and character are conceptualized on the basis of three types of memory and learning that have been described in humans. These are complex brain systems for behavioral conditioning (also called procedural learning of habits and skills), intentionality (including executive self-control for attaining goals, semantic learning of facts, and abstract symbolization), and self-awareness. Self-awareness includes constructive learning (i.e., recollection of the past and imagining the future), prospective learning (i.e., the encoding, storing, and retrieval of possible intentions), and the related capacities for a theory of mind (i.e., the ability to attribute mental states to ourself and others to facilitate empathic social interaction), the default mode (i.e., awareness of internal milieu without focus on external tasks), autobiographical memory (i.e., vivid recollection of past experiences with contextual awareness of when and where facts were learned), and story-telling (i.e., the meaningful composition of narrative figural art and language), which are all aspects of self-awareness and share largely overlapping brain circuitry. Temperament (the “emotional core” of personality) involves procedural memory regulated by complex distributed circuits in the cortico–striato–limbic system, primarily the cortical sensory areas, amygdala, and the caudate, and the putamen. Procedural memory underlies associative learning and involves presemantic perceptual processing of visuospatial information and affective valence that can operate independently of abstract conceptual and/or volitional processes. In contrast, intentionality involves higher cognitive functions of self-control, abstraction, and symbolization. These three systems of learning and memory can be dissociated functionally from one another but normally interact cooperatively so that habits, goals, and values can be integrated.

Neurobiologic studies of animals have been highly informative about the functional organization of brain systems underlying procedural learning and temperament. The explicit animal models that were originally described on the basis of extensive work in rodents and other nonprimates provided hypotheses that have recently been confirmed by extensive work in humans using modern techniques of brain imaging, neurochemistry, and neurogenetics. The most comprehensive neurobiologic model of learning in animals that has been systematically related to the structure of human temperament is summarized in Table 26–2. This model distinguishes four dissociable brain systems for behavioral inhibition (Harm Avoidance), behavioral activation (Novelty Seeking), social attachment (Reward Dependence), and partial reinforcement (Persistence).

The psychobiology of Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence is briefly described later.

HARM AVOIDANCE. Harm Avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and frustrative non-reward. It is observed as fear of uncertainty, shyness, social inhibition, passive avoidance of problems/danger, rapid fatigability, and pessimistic worry in anticipation of problems even in situations that do not worry other people. Adaptive advantages of high Harm Avoidance are cautiousness and careful planning when hazard is likely. The disadvantages occur when hazard is unlikely but still is anticipated, which leads to maladaptive inhibition and anxiety. People low in Harm Avoidance are carefree, courageous, energetic, outgoing, and optimistic, even in situations that worry most people. The advantages of low Harm Avoidance are confidence in the face of danger and uncertainty, leading to optimistic and energetic efforts with little or no distress. The disadvantages are related to unresponsiveness to danger or unrealistic optimism with potentially severe consequences when hazard is likely.

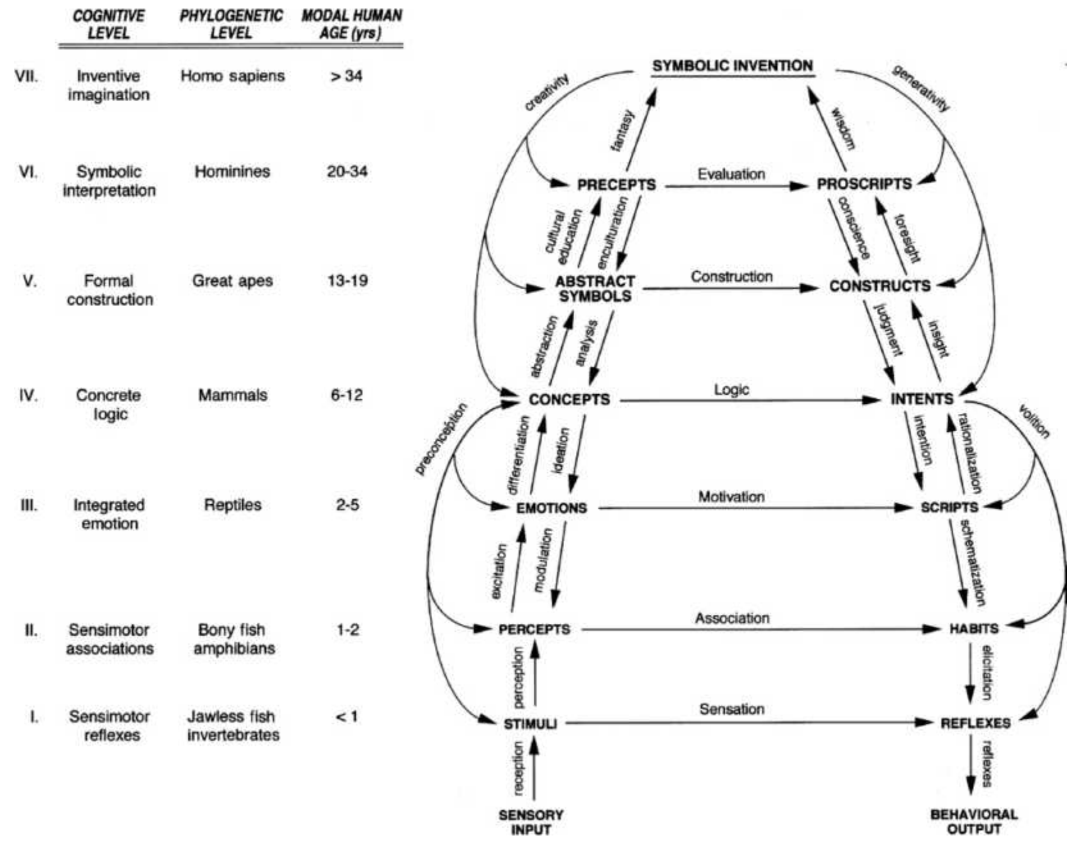

Table 26–2.
Four Dissociable Brain Systems Influencing Stimulus–Response Patterns Underlying Temperament

Brain System (Related Personality Dimension)	Principal Neuromodulators	Relevant Stimuli	Behavioral Response
Behavioral inhibition (Harm avoidance)	GABA Serotonin (dorsal raphe)	Aversive conditioning (pairing CS and UCS) Conditioned signals for punishment and frustrative non-reward	Formation of aversive CS Passive avoidance Extinction
Behavioral activation (Novelty seeking)	Dopamine	Novelty CS of reward CS or UCS of relief of monotony or punishment	Exploratory pursuit Appetitive approach Active avoidance Escape
Social attachment (Reward dependence)	Norepinephrine Serotonin (median raphe)	Reward conditioning (pairing CS and UCS)	Formation of appetitive CS
Partial reinforcement (Persistence)	Glutamate Serotonin (dorsal raphe)	Intermittent (partial) reinforcement	Resistance to extinction

CS, conditioned stimulus; GABA, γ-aminobutyric acid; UCS, unconditioned stimulus.

Adapted from *Cloninger CR. A systematic method for clinical description and classification of personality variants. A proposal. *Arch Gen Psychiatry*. 1987;44:573–588.

The psychobiology of Harm Avoidance is complex. In animal studies, ascending serotonergic projections from the dorsal raphe nuclei to the substantia nigra inhibit nigrostriatal dopaminergic neurons and are essential for conditioned inhibition of activity by signals of punishment and frustrative non-reward. Benzodiazepines disinhibit passive avoidance conditioning by gamma-aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei. The anterior serotonergic cells in the dorsal raphe nucleus intermingle with the dopaminergic cells of the ventral tegmental area, and both groups innervate the same structures (e.g., basal ganglia, accumbens, amygdala), providing opposing dopaminergic–serotonergic influences in the modulation of approach and avoidance behavior. The anterior serotonergic projections from the dorsal raphe to striatum, accumbens, amygdala and frontal cortex are usually associated with 5HT2 receptors. Individuals who are high in both Harm Avoidance and Novelty Seeking are expected to have frequent approach-avoidance conflicts, as seen in cycles of binging and purging in bulimia. More generally, excessive behavioral inhibition (i.e., high Harm Avoidance) predisposes individuals to anxiety, depression, and low self-esteem. Effective antidepressant treatment lowers scores in Harm Avoidance, but higher scores in Harm Avoidance predict poorer responses to antidepressants, including tricyclics and selective serotonin reuptake inhibitors.

Recent neuropsychological studies confirm that Harm Avoidance is associated with individual differences in classical aversive conditioning, whereas other dimensions of personality are uncorrelated (Table 26–3). Harm Avoidance, and not other dimensions of temperament, is also reliably associated with individual differences in startle responses: individuals who are high in Harm Avoidance have a greater startle response when they are viewing unpleasant stimuli, whereas those who are low in Harm Avoidance have a reduced startle response when they are viewing pleasant stimuli. Other neuropsychological tests also confirm that Harm Avoidance is associated with behavioral inhibition, as measured by Mismatch Negativity, an indicator of early preattentive sensory processing and automatic attention in orienting responses. Hence, the average effects of Harm Avoidance on startle obscure the important nonlinear interactions between predisposition and mental state. Likewise, Harm Avoidance is associated with the Posner validity effect (the Posner task uses a detection reaction time paradigm with the discrete presentation of simple visual stimuli in the periphery). Cues that correctly direct attention to the spatial location where the target stimulus will appear are called valid cues, whereas those that direct attention to incorrect locations are called invalid cues. In three large samples of healthy college students, those higher in Harm Avoidance had greater slowing of their reactions after invalid cues, or less benefit from valid cues, than others. Harm Avoidance is associated with greater sensitivity to the perception of fearful stimuli, which is mediated by strong functional connectivity between the amygdala and the anterior cingulate cortex. Even at rest, sustained fearful reactivity is sustained in people with the stable trait of Harm Avoidance, which is associated with reductions of slow oscillatory activity of the dorsal part of the medial prefrontal cortex in several independent studies.

Table 26–3.
Psychobiological Findings about Harm Avoidance

Variables	Observed Effects of High Harm Avoidance
Neuropsychology	
Aversive conditioning	Greater associative conditioning with punishment (*r* = 0.4)
Startle reflex	Potentiation of eye-blink response to aversive stimulus when HA is high and reduction when low
Fear perception	Greater sensitivity to fearful stimuli from stronger Amgydalar–Anterior Cingulate connectivity (*r* = 0.5)
Fear sustainment	Reduced slow low-frequency oscillations at rest in dorsomedial prefrontal cortex associated with greater amygdalar connectivity
Mismatch negativity	Greater amplitude of inhibiting early orienting response to deviant sounds in frontal cortex (*r* = –0.4)
Posner validity effect	Greater slowing of responses after invalid cues (*r* = 0.3)
Neuroimaging	
Insular salience network	Increased connectivity of right anterior insula with anterior cingulate cortex and dorsomedial prefrontal cortex
Amygdala activation	Increased sensitivity to fearful stimuli mediated by activation of amygdala and its connectivity with perigenual cingulate and dorsomedial prefrontal cortices
Volume of anterior cingulate cortex	Anterior cingulate cortex volume is larger in right and smaller in left hemisphere
Volume of cerebellar cortex	White matter and cortex smaller bilaterally
Mean diffusivity of striatum	Increased in pallidum bilaterally
Neurochemistry	
Platelet 5HT-2 receptor	Fewer receptors (*r* = –0.6)
Plasma GABA	Lower level (*r* = –0.5)
Neurogenetics	
5HT Transporter promoter gene	Greater reuptake activity
Tryptophan	Slower serotonin synthesis, especially in women reared in a

hydroxylase	hostile parental environment

Carriers of a gene that influences the activity of the serotonin transporter have increased Harm Avoidance, increased reactivity of the amygdala to fear, and increased risk of depression compared to others. Harm Avoidance scores explain 30% of the variance in the functional connectivity between the amygdala and perigenual anterior cingulate, which are involved in the perceptual processing of fearful stimuli. There is also a correspondence between structure and function: healthy human volunteers who are high in Harm Avoidance tend to have a greater volume of their right anterior cingulate gyrus and smaller volume of cerebellar white matter and cortex bilaterally (Table 26–3). Likewise, individual differences in Harm Avoidance are significantly negatively correlated with functional differences in activity in the dorsal part of the medial prefrontal network at rest in several independent studies. This includes significant negative correlations between regional blood flow and the score for Harm Avoidance in paralimbic regions, such as the left parahippocampal gyrus and the left orbitoinsular junction, and various neocortical regions in the frontal, parietal, and temporal cortex. Positron emission tomography at NIMH with 18-FDG in 31 healthy adult volunteers during a simple continuous Performance Task showed that Harm Avoidance was associated with increased activity in the anterior paralimbic circuit, specifically the right amygdala and insula, the right orbitofrontal cortex, and the left medial prefrontal cortex. Subsequent fMRI studies have confirmed that individuals with high levels of Harm Avoidance have increased sensitivity to fearful stimuli mediated by activation of the amygdala and its connectivity with the perigenual cingulate cortex and the dorsal part of the medial prefrontal cortex. This stress sensitivity network also interacts with the Insular Salience Network, which involves the right anterior insula and its connections with the anterior cingulate and the dorsomedial prefrontal cortex. This activation pattern corresponds well to the 5HT2 terminal projections of the dorsal raphe. However, 5HT2 has been measured only in platelets (see Table 26–3).

Higher plasma GABA levels have also been correlated with low Harm Avoidance. Plasma GABA has also been correlated with other measures of anxiety proneness and correlates highly with brain GABA levels. Finally, a gene on chromosome 17q12 that regulates the expression of the serotonin transporter has been found to account for 4% to 9% of the total variance in Harm Avoidance in most, but not all, of the tests of this relationship. These findings support a role for both GABA and serotonergic projections from the dorsal raphe underlying individual differences in behavioral inhibition as measured by the trait of Harm Avoidance.

NOVELTY SEEKING. Novelty Seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and escape from unconditioned punishment (all of which are hypothesized to covary as part of one heritable system of learning). This trait is called Novelty Seeking because its most distinctive feature is exploratory approach behavior, as confirmed by fMRI studies showing increased striatal dopamine release activated by novel stimuli regardless of whether they predict reward or not in people high in Novelty Seeking (Table 26–4). Novelty Seeking is observed as exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of frustration. Individuals high in Novelty Seeking are quick-tempered, curious, easily bored, impulsive, extravagant, and disorderly. Adaptive advantages of high Novelty Seeking are an enthusiastic exploration of new and unfamiliar stimuli, potentially leading to originality, discoveries, and reward. The disadvantages are boredom susceptibility, impulsivity, angry outbursts, potential fickleness in relationships, and impressionism in efforts. Persons low in Novelty Seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly. Their reflectiveness, systematic effort, and meticulous approach are clearly advantageous when these features are adaptively needed. The disadvantages reflect tolerance of monotony and lack of enthusiasm, potentially leading to prosaic routinization of activities.

Mesolimbic and mesofrontal dopaminergic projections have been shown to have a crucial role in incentive activation of each aspect of Novelty Seeking in animals. For example, dopamine-depleting lesions in the nucleus accumbens or the ventral tegmentum of rats and mice lead to neglect of novel environmental stimuli and reduce both spontaneous activity and investigative behavior. Behavioral activation by dopaminergic agonists is dependent on the integrity of the nucleus accumbens but not the caudate nucleus. In human studies, individuals at risk for Parkinson disease have low premorbid scores in Novelty Seeking but not other dimensions of personality, supporting the importance of dopamine in incentive activation of pleasurable behavior. The initiation and frequency of hyperactivity, binge eating, sexual hedonism, pathologic gambling, Internet addiction, drinking, smoking, and other substance abuse, especially stimulants, are each associated with high scores in Novelty Seeking.

The psychobiological correlates reported for Novelty Seeking are summarized in Table 26–4. High scores correlate with greater capacity for synthesis of dopamine in the ventral striatum and reduced D2/D3 autoreceptor availability in the substantia nigra and ventral tegmental area in the midbrain, thereby leading to accentuated dopaminergic responses to novelty and other conditions that induce dopamine release. Human functional neuroimaging studies also show that the high Novelty Seekers have greater functional connectivity with the hippocampus, amygdala, and orbitofrontal cortex in response to novel stimuli than other people. Structural imaging studies indicate that people with higher Novelty Seeking have larger left posterior cingulate gray matter volumes and smaller inferior frontal gray matter volumes.

Evoked potential studies confirm that Novelty Seeking is associated with greater cortical reactivity and augmentation of stimulus intensity in response to somatosensory and novel stimuli. Novelty Seekers are also sensitive to both sedatives and stimulants: they are easily oversedated by benzodiazepines and overstimulated by amphetamines, leading to deterioration in their information processing. Their reaction times are slow to neutral stimuli, but they show a greater approach to novel stimuli, whether these predict reward or not.

Table 26–4.
Psychobiological Findings about Novelty Seeking

Variables	Observed Effects of High Novelty Seeking
Neuropsychology	
Reinforcement learning	More approach to novel stimuli and slower to react to neutral stimuli
Neocortical reactivity	Greater cortical reactivity to somatosensory (MEG) and novel stimuli (ERP)
Striatal–mediated behavioral activation	Greater striatal dopamine release activated by novel stimuli that do not predict reward
Impulsive decision making	Greater ventromedial prefrontal cortical activity at rest leads to reduced delay of gratification
Cortisol response to stress	Reduced at rest and after social stress
Neuroimaging	
Connectivity of ventral striatum	Greater connectivity with hippocampus, amygdala, and orbitofrontal cortex is activated by novel stimuli
Insular salience network	Reduced activity
Posterior cingulate volume	Greater gray matter volume in left hemisphere
Inferior frontal cortex volume	Smaller gray matter volume bilaterally
Neurochemistry	
Ventral striatal dopamine synthesis	Greater synthesis capacity ($r = 0.8$)
Midbrain dopamine autoreceptors	Reduced autoreceptor availability in substantia nigra/ventral tegmental area of midbrain, leading to more rapid sensitization to stimulants
Dopamine DRD2 receptor	Negative correlation of Novelty Seeking with DRD2 levels in insula bilaterally in parkinsonism
Neurogenetics	
Dopamine transporter gene	Greater reuptake activity
Dopamine DRD2 receptor gene	Moderates development of higher adult Novelty Seeking in response to harsh discipline in childhood

The association of increased striatal dopamine release in response to novel stimuli with high Novelty Seeking is more specifically associated with a higher density of the dopamine transporter, suggesting that Novelty Seeking involves increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Novelty Seeking leads to impulsive decision making and various pleasure-seeking behaviors, including cigarette smoking, which may explain the frequent observation of low platelet MAO B activity because cigarette smoking has the effect of inhibiting MAO B activity in platelets and in the brain.

Studies of candidate genes involved in dopamine neurotransmission (e.g., dopamine transporter and D4DR) have provided evidence of association with Novelty Seeking and no other dimension of temperament. The dopamine transporter, which is responsible for the presynaptic reuptake of dopamine and a major site of action of drugs, including stimulants such as methylphenidate, is encoded by a gene locus on chromosome 5p. Polymorphisms at this gene locus are associated with Attention-Deficit Disorder and other disorders related to variation in Novelty Seeking. Likewise, polymorphisms at the DRD4 locus have been associated with Attention-Deficit Disorder, opioid dependence, and other traits related to Novelty Seeking.

REWARD DEPENDENCE. Reward Dependence reflects a heritable bias in the maintenance of behavior in response to cues of social reward. Reward dependence is characterized by sentimentality, social sensitivity, attachment, and dependence on approval by others. Individuals high in Reward Dependence are tender-hearted, sensitive, dedicated, dependent, and warmly sociable. One of the major adaptive advantages of high Reward Dependence is the sensitivity to social cues, which facilitates affectionate, social relations, and genuine care for others. The disadvantage is related to suggestibility and loss of objectivity frequently encountered with people who are excessively socially dependent. Individuals low in Reward Dependence are practical, tough-minded, cold, socially insensitive, irresolute, and indifferent if alone. The advantages of low Reward Dependence are personal independence and objectivity not corrupted by efforts to please others. Its adaptive disadvantage is related to social withdrawal, detachment, and coldness in social attitudes.

Noradrenergic projections from the locus coeruleus and serotonergic projections from the median raphe are proposed to influence such reward conditioning (Table 26–2). In animals, stimulation of the noradrenergic locus coeruleus or its dorsal bundle, or direct application of norepinephrine, decreases the firing rate of terminal neurons and increases their sensitivity to other afferents so that targeted stimuli can stand out from nontargeted stimuli. In humans, short-term reduction of norepinephrine release by acute infusion of the alpha-2 presynaptic agonist clonidine selectively impairs paired-associate learning, particularly the acquisition of novel associations. The noradrenergic locus coeruleus is located at the same posterior level of the brainstem as the serotonergic median raphe, and both of these posterior monoamine cells innervate structures important to the formation of paired associations, such as the thalamus, neocortex, and hippocampus. Neurophysiologic studies show that the anterior temporal lobe decodes social signals, such as facial images and social gestures. Consequently, individuals high in Reward Dependence are expected to be particularly sensitive in their social communication, whereas those low in Reward Dependence are expected to be socially aloof. The “love hormone” oxytocin is released in response to sexual orgasm, and its plasma level is positively correlated ($r = 0.5$) with individual differences in Reward Dependence but not other dimensions of personality.

The psychobiological correlates reported about Reward Dependence are summarized in Table 26–5. As predicted, Reward Dependence is associated with individual differences in the formation of conditioned signals of reward. This is also supported by its association with individual differences in paired-associate learning. People who are high in Reward Dependence also show greater discrimination of facial emotions and social cues, which is mediated by their having larger oxytocinergic regions in the hypothalamus. In individuals with high Reward Dependence, the oxytocinergic regions of the hypothalamus have reduced connectivity with the amygdala, septum, and dorsal anterior cingulate in response to perceptual processing of facial emotions and social cues. Reward Dependence is also associated with greater opioid receptor availability in the ventral striatum bilaterally. Consequently, people who are high in Reward Dependence have readily form warm and caring attachments to other people.

Table 26–5.
Psychobiological Findings about Reward Dependence

Variables	Observed Effects of High Reward Dependence
Neuropsychology	
Reward conditioning	Enhanced associative pairing with rewards and not novelty without reward
Paired associates	Better learning of paired associations
Posner validity effect	Faster responses after valid cues
Perceptual processing of facial emotions and social cues	Better discrimination of facial emotions mediated by variability of regional oxytocin receptor activity
Mismatch negativity	Greater latency of preattentive MEG response to changes in tonal duration in left hemisphere
Neuroimaging	
Corticostriatal system	Greater gray matter volume and connectivity of striatum (caudate) with orbitofrontal cortex and temporal lobes
Caudate volume and activity	Greater size and activity
Oxytocinergic system	Larger oxytocinergic regions in hypothalamus with reduced connectivity to amygdala, septum, and dorsal anterior cingulate, which is a network activated by perceptual processing of facial emotions and social cues
Neurochemistry	
Striatal opioid availability	Greater opioid receptor availability in ventral striatum bilaterally
Plasma oxytocin	Higher oxytocin levels ($r = 0.5$)
Plasma cortisol	Higher morning cortisol when depressed ($r = 0.3$)
Neurogenetics	
5HT2 c receptor	Allelic association (effect size 2.0)
Epidermal growth factor	Epidermal growth factor A61G G/G polymorphism associated with higher RD in men

PERSISTENCE. Persistence reflects a heritable bias in the maintenance of behavior despite the frustration, fatigue, and intermittent reinforcement. It is observed as industriousness, determination, ambitiousness, and perfectionism. Highly Persistent people are hardworking, perseverant, and ambitious overachievers who tend to intensify their effort in response to anticipated reward and perceive frustration and fatigue as a personal challenge. High Persistence is an adaptive behavioral strategy when rewards are intermittent, and contingencies remain stable. When the contingencies change rapidly, perseveration becomes maladaptive. Individuals low in Persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest a low level of perseverance even in response to intermittent reward. Accordingly, low persistence is an adaptive strategy when reward contingencies change rapidly and may be maladaptive when rewards are infrequent but occur in the long run.

Persistence can be objectively measured by the partial reinforcement extinction effect (PREE), in which persistent individuals are more resistant to the extinction of previously intermittently rewarded behavior than other individuals who have been continuously reinforced. Earlier work in rodents showed that the integrity of the PREE depends on projections from the hippocampal subiculum to the nucleus accumbens. This glutaminergic projection may be considered as a short circuit from the behavioral inhibition system to the behavioral activation system, thereby converting a conditioned signal of punishment into a conditioned signal of anticipated reward. This connection is probably disrupted in humans by lesions of the orbitomedial cortex that may have a specific antipersistence effect of therapeutic benefit to some patients with severe obsessive-compulsive PD. Bilateral cingulotomy, which reduces Harm Avoidance only, is less effective in reducing persistent compulsive behavior than cingulotomy combined with orbitomedial lesions.

These findings in animals suggested that the regulation of Persistence involved the ventral striatum, which includes the nucleus accumbens. This has been tested in humans and confirmed (Table 26–6). Individual differences in persistence are strongly correlated (r = 0.8) with responses measured by fMRI in a circuit involving the ventral striatum, orbitofrontal cortex/rostral insula, and dorsal anterior cingulate cortex (BA 32). Subjects low in persistence exhibited relative decreases in activity within this circuit, whereas those high in persistence exhibited relative increases. Persistence scores also correlated with apparent selection bias, such that subjects with high persistence scores made relatively more pleasant judgments at the expense of neutral judgments when viewing pictures from the International Affective Picture System.

Motivation

According to materialistic theories of personality, survival and reproduction are the basic drives for all animal species, including human beings. These are expressed in humans primarily through affects and emotions, which are derived from their experiences. In contrast to the limited motivational spectrum of the basic drives, emotions have an independent motivational power that makes them the primary motivational system for many people, including the personality processes that materialists use to seek satisfaction and meaning, albeit without enduring success because seeking satisfaction from what you cannot possess or control is ultimately disappointing (e.g., greed is insatiable, and nobody lives forever or without suffering).

Nevertheless, it is useful to recognize that the temperament traits of Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence, with their associated emotions of fear, anger, attachment, and ambition, are observable early in development. Research in children has demonstrated that, during the first several months of life, fear and anger differentiate from the disposition to distress (a tendency to become upset and autonomically aroused easily and intensely). During this period, which is characterized by active regressive changes in the organization of neuronal circuits and density of synapses, especially in frontal, temporal, and limbic cortical areas, many other complex and social functions in human behavior emerge. These new functions are, however, organized around an early set of moderately stable but modifiable behavioral and emotional dispositions referred to in this work as temperament traits.

A relatively limited spectrum of basic emotions is associated with the four temperament traits (Table 26–7). Depending on whether a particular temperament trait is high or low, certain emotions will tend to dominate one’s motivation, perception, and behavior, particularly when a person’s character is not yet highly developed.

Table 26–6.
Psychobiological Findings about Persistence

Variables	Observed Effects of High Persistence
Neuropsychology	
Partial reinforcement extinction effect (PREE)	Greater resistance to extinction (quitting effort to obtain a goal) despite frustration from infrequent reward with high persistence
Positively biased reward perception	Neutral stimuli perceived as rewards
Cortical reactivity	Reduced cortical excitability at rest
Phonemic mismatch negativity	Greater strength of preattentive response to infrequent vowel sounds
Rey word list learning	Better learning without reinforcement
Intelligence and achievement	Higher academic achievement and slightly higher IQ
Neuroimaging	
Reward-seeking system	Greater activation of circuit involving ventral striatum, lateral orbitofrontal cortex (BA 47), and anterior cingulate in response to intermittent rewards, giving rise to the PREE
Striatal-mOFC connectivity	Greater connectivity of striatum and medial orbitofrontal cortex (mOFC)
Hippocampal–accumbens pathway	Glutaminergic projection from subiculum to nucleus accumbens is essential to PREE
Neurochemistry	
Salivary alpha-amylase activity	Greater noradrenergic arousal on average (whether at rest or stressed)
Neurogenetics	
Interaction of DAT1 and 5HT2a	Greater persistence is associated with interaction of dopamine transporter (DAT1) and serotonin receptor 5HT2A
Brain-derived neurotrophic factor	Association with Val66Met polymorphism modulates the effects of parental rearing

Table 26–7.
Effects of Positive (+) and Negative (–) Reinforcement on Emotional State of Four Temperaments

Temperament Dimension	High Scorers		Low Scorers	
	+	–	+	–
Harm avoidance	Anxious (agitated)	Depressed (retarded)	Cheerful	Fearless
Novelty seeking	Euphoric	Angry	Placid	Stoical
Reward dependence	Sympathetic	Disgusted	Aloof	Indifferent
Persistence	Enthusiastic	Steadfast	Unstable	Discouraged

As can be inferred from Table 26–7, the same external stimulus is likely to elicit responses via activation of multiple temperament dimensions. For example, novel or unfamiliar stimuli elicit interest in approach in proportion to Novelty Seeking, as well as inhibition of approach in proportion to Harm Avoidance. Consequently, people who are high in both Novelty Seeking and Harm Avoidance experience approach-avoidance conflicts, as seen in bulimics who binge and purge. Each temperament trait clearly involves an integration of multiple emotional drives that may be conflicting (competitive) or facilitatory (synergistic), particularly when a person is not fully self-actualized (i.e., when their habits are not yet congruent with their goals and values).

In contrast, dualistic theories of personality recognize that both the analytical mind (the intentional self) and temperament have an important influence on a person's motivation (i.e., what they want to do in life). According to this perspective, temperament involves a relatively small set of emotions associated with one's basic needs, for example, safety, which are called primary motives. Excessive fear and anger, associated with temperament, are then regarded as motivationally monopolistic and thought to take over the personality by altering perception, learning, and behavior in a biased way. However, under normal circumstances, after survival needs are met, the goals of normally developing personality change to include not only the integrity of the physical self but also the strength and integrity of the analytical mind or mental self (e.g., self-esteem). The mental self also allows adaptation to numerous social goals (e.g., education, occupation, family) and a rich spectrum of secondary (social) emotions (such as shame and compassion). These "secondary," "social," or "growth" motives are closely functionally related to character development according to non-materialistic (i.e., dualistic and holistic) models. Specifically, basic emotions of fear, anger, and excitement are transformed into more complex secondary emotions, such as carefulness, assertiveness, and joy, through the interaction with increasingly more complex internalized concepts associated with character. Although some basic character components develop early in life, such as trust and confidence, it is the completion of self-object differentiation (“Me” vs. “Not me”) between 18 months and 3 years of age that sets the stage for the later development of character traits and secondary emotions with an allocentric perspective, such as empathy, which emerges around age 7 years.

The secondary emotions may take over as primary motivators of further character development and maturation. Of note, they are not as monopolistic as the basic emotions and thus motivate the development of more flexible and adaptable personality traits. As shown in Table 26–8, each of the three character traits is associated with a typical pattern of secondary emotions.

Table 26–8.
Effects of Positive (+) and Negative (–) Reinforcement on Emotional State of Three Characters

Character Dimension	High Scorers		Low Scorers	
	+	–	+	–
Self-directed	Hopeful	Resourceful	Vain	Shameful
Cooperative	Loving	Forgiving	Scornful	Revengeful
Self-transcendent	Joyful	Peaceful	Greedy	Miserable

According to materialistic and dualistic models of motivation, abnormal (deviant, immature) motivation derives from two or three dominant, monopolistic elementary emotional needs associated with survival. In contrast, more mature motivation develops after basic needs are met, and the person is freed to experience numerous secondary motives for growth in character and in self-awareness. This could explain the motivational inflexibility and poverty of deviant personality and account for some of the rich motivational diversity and flexibility of people with mature self-control. However, executive functions and analytical reasoning do not explain the early emergence of self-transcendent features in children, such as trust. Nor does it really explain the personal motive to serve others or to make sacrifices that do not benefit the individual. It is important to recognize the need for cultivating self-transcendence throughout life for two reasons: (i) If self-transcendent motives are not basic, there is no potential for self-transcendence because something cannot arise from nothing; and (ii) If self-transcendent motives are basic but are not nurtured from the beginning, they are likely to wither and be ignored later, just as happens when the gifts of child prodigies are not cultivated. Fortunately, self-transcendent motives such as trust and love are basic aspects of life along with basic drives for purpose, meaning, and coherence in modern humans. Much research shows that symbiosis and cooperation are more basic motives in all life forms than fear and competition.

Empirically, any temperament profile can lead to well-being with healthy character development. Temperaments are only monopolistic when they are not integrated with regulatory character strengths.

Character

Character refers to the mind, that is, the conceptual core of personality. It involves individual differences in self-concepts and human relations that reflect personal goals and values. In other words, character is what individuals make of themselves intentionally and/or creatively. Character is rational and volitional. Whereas temperament involves basic emotions such as fear and anger, character involves secondary emotions such as empathy and shame, and, in self-transcendent individuals, virtues in action such as practical wisdom, hope, and compassion. As a result, character can be described as one's mental self-government, which involves executive, legislative, and judicial functions. In what follows, the concept of character is outlined on the basis of the seven-factor psychobiological model of personality, which is also called the biopsychosocial model, to emphasize the three processes of human learning that comprise personality. The psychodynamic concept of character, which has contributed many illuminating clinical and theoretical formulations from a dualistic perspective, is discussed in some detail as well.

Psychobiology of Character. Character (or the "conceptual core" of personality) involves higher cognitive functions, which are organized as two of the three human systems of learning and memory. Whereas temperament involves behavioral conditioning and procedural memory, character involves the brain networks for intentionality and self-awareness. The human system for intentionality including executive self-control for attaining goals, semantic learning of facts, and abstract symbolization. The human system for self-awareness includes constructive learning (i.e., recollection of the past and imagining the future), prospective learning (i.e., the encoding, storing, and evaluation of possible intentions), and the related capacities for the theory of mind (i.e., the ability to attribute mental states to ourself and others to facilitate empathic social interaction), the default mode (i.e., awareness of internal milieu without focus on external tasks), autobiographical memory (i.e., vivid recollection of past experiences with contextual awareness of when and where facts were learned), and story-telling (i.e., the meaningful composition of narrative figural art and language), which are all aspects of self-awareness and share largely overlapping brain circuitry.

All three systems are strongly related to personality, and they naturally interact to allow a person to adapt to changing circumstances and emerging opportunities. Such synergistic interactions mean that healthy human function cannot be reduced to materialistic models, as advocated by some molecular biologists, or to dualistic models, as advocated by some cognitive-behavioral or psychodynamic therapists. The brain networks for emotional reactivity, intentionality, and self-awareness function interdependently, not separately. They integrate information from all parts of the brain into a more-or-less coherent whole in self-awareness, and to do so requires insight into what is really valuable combined with the plasticity to change in order to moderate their appetites and habits. Put another way, materialistic approaches that treat a person’s brain and other parts of the body with medications may transiently mask symptoms to stabilize but do not help a person to learn how to live well. Likewise, dualistic approaches, which treat both behavioral and intellectual aspects of PD, do not allow people to let go of their struggles with themself and others. Healthy awareness depends on synergistic interactions among brain systems for self-awareness, intentionality, and behavioral conditioning. Well-being requires the wisdom to know what is good for yourself and others, the willingness to change flexibly, and the creativity and perseverance to find a way to achieve your valued goals. To understand this, it is useful first to describe the phenotypic components of character.

The executive, legislative, and judicial functions of mental self-government can be measured as three distinct character traits, which are called Self-Directedness, Cooperativeness, and Self-Transcendence, respectively. These character traits are adaptive, but their low ends are less advantageous because there are few circumstances in which low character development is adaptive, even temporarily. Self-Directedness quantifies differences in the executive competence of individuals. A highly self-directed person is self-sufficient, responsible, reliable, resourceful, goal-oriented, and self-accepting. The most advantageous summary feature of self-directed individuals is that they are realistic and effective; that is, they are able to adapt their behavior in accord with individually chosen, voluntary goals. Individuals low in Self-Directedness are blaming, helpless, irresponsible, unreliable, reactive, and unable to define, set, and pursue internally meaningful goals. Such poor executive function, manifest as unrealistic behavior and lack of internal guidance, is rarely advantageous to the individual.

Cooperativeness quantifies differences in the legislative functions of individuals. That is, Cooperativeness allows people to make the rules and follow the principles by which they get along with other people. Highly cooperative people conceptualize themselves as integral parts of human society. Such highly cooperative persons are described as tolerant, helpful, empathic, principled, and compassionate. These features are advantageous in teamwork and social groups but not for individuals who must live in a solitary manner. People who are low in Cooperativeness are intolerant, unhelpful, self-absorbed, opportunistic, unforgiving, and revengeful. They primarily look out for themselves and tend to be hostile and inconsiderate of other peoples’ rights or feelings.

Self-Transcendence quantifies individual differences in the judicial functions of people. In other words, Self-Transcendence allows one to recognize when various rules apply in a particular context (i.e., in the narrative of intersecting lives). Self-Transcendence reflects the extent to which people conceptualize themselves as an integral part of the universe as a whole. Self-transcendent individuals are described as judicious, insightful, idealistic, contemplative, and spiritual. These traits are adaptively advantageous when people are confronted with ultimate situations such as suffering, illness, or death, which is inevitable with advancing age. They may appear disadvantageous in secular, materialistic societies where idealism, modesty, and meditative search for meaning might interfere with the acquisition of wealth and power. People low in Self-Transcendence tend to be pragmatic, objective, materialistic, controlling, and pretentious. Such individuals appear to fit in well in most Western societies because of their pragmatism and materialistic ambitions. However, they consistently have difficulty accepting suffering, failures, personal and material losses, and death, which leads to a lack of serenity and adjustment problems, particularly with advancing age.

Contrasting sets of descriptors that distinguish high and low scorers are shown in Table 26–9. High and low scorers in each character dimension are distinguished by behavior traits that arise from differences in concepts that are each internally consistent but not logically falsifiable. For example, people low in Self-Transcendence live in the material world, skeptical of whatever they cannot prove objectively and use practically. In contrast, for highly Self-Transcendent individuals, the meaning of life goes beyond material things and includes intuitive awareness of what is beautiful, true, and good, to which materialists may be insensitive. Each set of beliefs appears to be internally consistent to those who hold them, who also regard their approach to life as realistic.

However, firm beliefs may lead to an identity that is long-lasting, but they are not a sufficient basis for well-being or the coherence of our habits, goals, and values with our human nature and the reality of all-being. The development of an authentic sense of identity cannot be determined by accepting or rejecting what others want us to believe and do. Each person must look within themselves to perceive and understand their own nature, what satisfies them, and what they find meaningful. We can only cultivate a personality that promotes well-being by learning the answers to these questions about life for ourselves. Each of us may differ in our initial intuitions about what is real, satisfying, and meaningful, but we can also learn by comparing our initial understanding to the scientific observations about the three aspects of human personality and the development of well-being. That way, we can learn from the objective and subjective experiences of others while relying ultimately on our own insight and judgment. Life is a wonderful opportunity to explore and discover what truly exists, what we can understand, and what is valuable and meaningful. Character develops in a stepwise manner in incremental shifts from infancy through late adulthood. Under health-promoting conditions, it develops along a path of increasing awareness leading to maturity and coherence. The timing and rate of transitions between levels of maturity are nonlinear functions of antecedent temperament configurations, systematic cultural biases, and experiences unique to each individual, which depend on individual differences in episodic memory or intuitive self-awareness that enables human beings to recollect past experiences and imagine future activities. Dualistic theories regard developing character traits as merely newly internalized concepts about one's self and the external world designed to optimize adaptation of temperament (i.e., early emotionality) to the environment by reducing discrepancies between one's emotional needs and norm-favoring social pressures. In contrast, research and treatment with the biopsychosocial model now recognizes that developing character strengths are inspired by our understanding of virtue and by our creativity in finding ways to express that insight in action flexibly so that our habits, goals, and values are congruent with our understanding of reality as a whole.

Table 26–9.
Descriptors of Individuals Who Score High and Low on the Three Character Dimensions

Character Dimension	Descriptors of Extreme Variants	
	High	**Low**
Self-Directedness	Responsible	Blaming
	Purposeful	Aimless
	Self-accepting	Vain
	Resourceful	Passive
	Spontaneous	Conflicted
Cooperative	Tolerant	Intolerant
	Empathic	Insensitive
	Helpful	Selfish
	Compassionate	Revengeful
	Principled	Opportunistic
Self-Transcendent	Self-forgetful	Self-preoccupied
	Transpersonal	Self-centered
	Spiritual	Skeptical
	Contemplative	Objective
	Idealistic	Pragmatic

In Figure 26–1, character corresponds to the processes of logic, construction, and evaluation of abstract symbols that are based on a conceptual representation of information and are well developed only in some mature humans. These processes are related to executive functions (predominantly logic), legislative functions (predominantly construction), and judicial functions (predominantly evaluation). Early fMRI research in healthy human volunteers by Debra Gusnard and Marc Raichle demonstrated a strong correlation between Self-Directedness and a cortical circuit involving the medial prefrontal cortex, which is known to regulate executive function (see Cloninger, 2004). Earlier work also showed that psychophysiological markers of neocortical processing, such as the P300 event-related potential and Contingent Negative Variation, are correlated with measures of character but not temperament. Namely, Self-Directedness, but not temperament traits, correlates moderately with the evoked potential P300 ($r = 0.4$, $P < .002$). Likewise, Cooperativeness correlates with the Contingent Negative Variation (this was particularly obvious for the Empathy subscale, $r = 0.4$). Individuals with Parkinson disorder differ in temperament from others (they are lower in Novelty Seeking premorbidly) but not in character. These early fMRI and ERP findings have been confirmed and extended by recent structural and functioning neuroimaging findings demonstrating that character involves higher cortical functions instantiated in specific neocortical networks of learning and memory (Table 26–10). The executive and legislative functions related to Self-Directedness and Cooperativeness involve conceptual processing in components of the intentional learning system, which recognize and appraise the feelings and intentions of one's self and of others. In contrast, Self-Transcendence involves the functioning of the autobiographical memory system that allows self-aware (autobiographical) learning and memory functions with a holistic narrative perspective, including mental time-travel, vivid recollection, and imagination of the past and future as a continuity, and identity formation as a creative process.

Table 26–10.
The Relationship between Character Traits, Higher Cognitive Functions, and Brain Structures Based on Voxel-Based Morphometry

Character Dimension	Higher Cognitive Function	Associated Brain Structures
Self-Directedness	Executive functioning Evaluation of internal cues Self-reflection Appraisal of the self and personal intentions	Executive brain network including Anterior cingulate cortex, Posterior cingulate cortex Medial prefrontal cortex Temporal cortex (for self-appraisal)
Cooperativeness	Legislative functioning Empathy Metacognition Appraisal of others' feelings and intentions	Legislative brain network including Medial frontal cortex (white matter) Precentral gyrus (white matter) Superior temporal gyrus (gray matter, BA22)
Self-Transcendence	Judicial functioning Autobiographical recollection Mental time-travel Holistic perspective shifting (time, place, person) Imagination of possible future events in vivid detail in place and time Transpersonal identification	Judicial brain network involves autobiographical memory and learning, including Middle temporal gyrus (greater GMV of BA 21) Inferior parietal gyrus (greater GMV of BA 40) Superior frontal gyrus in medial prefrontal cortex (smaller GMV of BA 10)

Data from Gardini S, Cloninger CR, Venneri A. Individual differences in personality traits reflect structural variance in specific brain regions. *Brain Res Bull.* 2009;79(5):265–270; and Van Schuerbeek P, Baeken C, De Raedt R, De Mey J, Luypaert R. Individual differences in local gray and white matter volumes reflect differences in temperament and character: a voxel-based morphometry study in healthy young females. *Brain Res.* 2011;1371:32–42.

Consequently, it is useful to distinguish three major aspects of human personality: temperament, character, and identity. The characteristics of temperament, character, and identity are summarized in Table 26–11. A person's identity is cultivated and formed in autobiographical memory, which integrates a person's emotional drives (temperament) with their emerging goals and values (character). Identity is the narrative self in the context of a self-aware individual developing over time in a variety of situations. Identity, character, and temperament are continuously influencing one another as personality develops over the lifespan and are also responsive in more or less adaptive ways to changes in life situations and events, including changing social roles with age, marriage, and work, as well as traumatic and therapeutic experiences.

Table 26–11.
Key Differences between Temperament, Character, and Identity

Variable Properties	Temperament	Character	Identity
Awareness level	Automatic	Intentional	Self-aware
Memory form	Percepts Procedures	Concepts Propositions	Intuitions Narratives
Learning principle	Associative conditioning	Logical/conceptual analysis	Automatic Intelligence
Role of subject in mental activity	Passive Reproductive	Active effort and logical construction	Effortless and fluid creativity
Key brain system	Limbic systems Corticostriatal habit system	Semantic memory (frontotemporal neocortex)	Autobiographic/autonoetic memory system
Form of mental representation	Stimulus-response sequences varying additively in strength	Logical hierarchies following from assumptions, prior goals, and values	Narrative schema and interactive networks varying qualitatively in configuration

Genomic Approaches to Understanding Temperament and Character. Personality development, including identity formation, in particular, involves the adaptive development and integration of temperament and character in the changing situations and roles of a person's life. How do temperament and character develop? What are the mechanisms that allow adaptive learning across the lifespan in relation to temperament and character? These basic questions have been matters of speculation in the past, but, as described briefly in the introduction, Zwir, Cloninger, and their associates have made much progress in uncovering the hidden mechanisms by carrying out person-centered Genome-wide Association Studies (GWAS) of temperament and character to learn what genes are associated with temperament only, character only, and the interactions of both temperament and character together. The method of person-centered GWAS allows for gene–gene and gene–environment interactions. Different profiles of temperament and of character were associated with different sets of functionally interacting genes detected through single-nucleotide polymorphisms. The broad heritability of the various traits of personality are all around 50%, but this depends on substantial interactions among multiple genes and environmental variables. The average effects of individual genes explain less than 1% of the variability in personality, but gene–gene interactions and gene–environmental interactions account well for the broad heritability of temperament and character. The whole genome was screened for specific genes using about 1 million single-nucleotide polymorphisms in more than 4,000 people representative of the general populations of Finland, Germany, and Korea. Personality was found to be highly polygenic, with the associated genes distributed across all the human chromosomes. Figure 26–2 shows the number of genes per chromosome that are strongly associated with clusters of people with particular temperament profiles (i.e., temperament only), clusters of people with particular character profiles (i.e., character only), and clusters of people with profiles of both temperament and character traits (i.e., temperament and character). Sets of multiple genes were identified independent of information about the personality traits, and the clusters of people were identified without information about the genetic profiles. The gene sets, therefore, represent naturally occurring combinations of genes with distinct functional interactions. The clusters of personality traits represent attractor states in a complex adaptive system, allowing people to function in a particular situation more or less well, as illustrated in the figures that follow next. The sets of genes and the personality profiles were very strongly associated, but the relationships were complex in the sense that the same gene set could be expressed in multiple ways (i.e., multifinality, pleiotropy), and different sets of genes could be expressed in the same way (i.e., equifinality, heterogeneity).

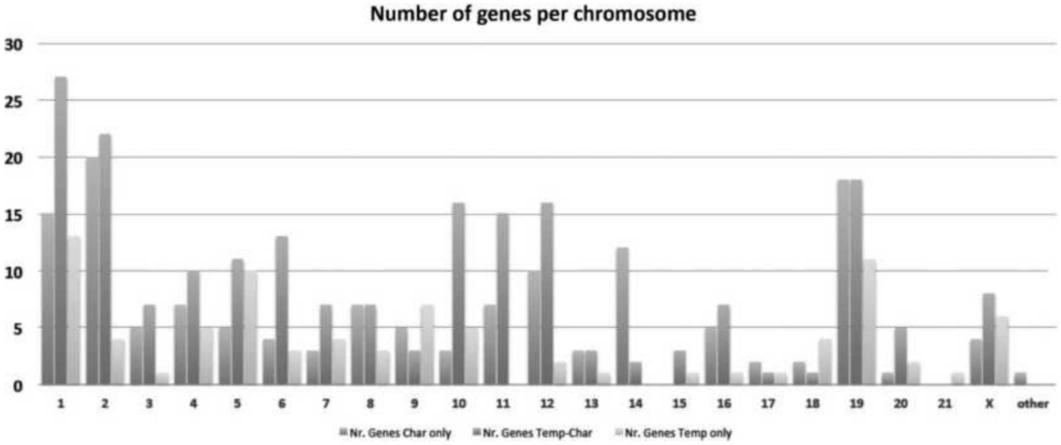

FIGURE 26–2. Number of genes per chromosome strongly associated with temperament profiles only (temp only), character profiles only (char only), and the interaction of both temperament and character (temp and char) in person-centered GWAS of the temperament and character inventory. (Used with permission of the Anthropedia Foundation.)

	lncRNA	ncRNA	protein coding	pseudogene	others
Char-only	29.49	7.19	41.73	13.67	7.92
Temp-only	20.00	7.06	48.24	14.12	10.59
Temp-Char	19.80	5.94	46.03	15.84	12.37

FIGURE 26–3. Percentage of different types of genes strongly associated with temperament profiles only (temp only), character profiles only (char only), and the interaction of both temperament and character (temp and char) in three independent samples (Finland, Germany, and Korea). (Used with permission of the Anthropedia Foundation.)

The complex development of personality profiles from interacting sets of multiple genes and environmental variables will be described in more detail later. Now it is fundamentally important to recognize that most of the genes that influence personality have regulatory functions rather than being protein-coding genes (Fig. 26–3). In older genetic studies of personality, nearly all attention has been focused on protein-coding genes related to neurotransmitter function or neurotropin functions like those mentioned for temperament traits in tables. However, it is the regulatory genes that actually help to understand the change and development of human personality. In fact, 95% of the 267 genes that are found in modern Homo sapiens, but not in Neanderthals or chimpanzees are RNA genes that do not encode proteins, as shown in Figure 26–4. These regulatory

RNA genes account for the emergence of human self-awareness, creativity, and prosocial behavior that allowed modern humans to be more adaptable than other hominids. These findings confirm that nearly all differences among Homo sapiens, Neanderthals, and chimpanzees lie in the regulation of the expression of genes that encode proteins.

Most of the regulatory genes unique to modern humans are long non-coding RNAs (lncRNAs), other shorter non-coding RNAs, and pseudogenes. These non-coding RNAs (ncRNAs) are functional RNA molecules that are transcribed from DNA but are not translated into proteins. They can regulate gene expression at both the transcriptional and posttranscriptional levels. They are involved in epigenetic processes that can be divided into two main groups: the short ncRNAs of less than 30 nucleotides and the long ncRNAs of more than 200 nucleotides. The major classes of short ncRNAs are microRNAs (miRNAs), short interfering RNAs (siRNAs), and piwi-interacting RNAs (piRNAs). Both long and short RNAs are known to play a role in heterochromatin formation, histone modification, DNA methylation targeting, and gene silencing. However, lncRNAs and the shorter ncRNAs act differently.

Nearly 30% of the genes associated with character only involve lncRNAs, whereas the percentage is only 20% in the other two groups, as shown in Figure 26–3. In contrast, protein-coding genes are more often associated with temperament only than with the groups involving character. The more prominent role of lncRNAs in character than for temperament is consistent with the greater importance of epigenetic change for the development and maintenance of all aspects of well-being across the human lifespan. The human capacity for healthy longevity permits humans to have extended periods of learning early in life in order to accumulate knowledge and understanding, which is a remarkable feature of modern humans and their complex social relationships. This genomic finding supports findings from longitudinal studies that character shows much greater change during young adulthood than does temperament. LncRNAs form extensive networks of ribonucleoprotein (RNP) complexes with numerous chromatin regulators. These chromatin regulators target these enzymatic activities to the appropriate locations in the genome. Apparently, lncRNAs can function as modular scaffolds to specify higher-order organization in RNP complexes and in chromatin states. LncRNAs have several functions in the regulation of gene transcription, including the regulation of specific gene transcription (either activation or repression), posttranscriptional regulation, differential spicing, and regulation of epigenetic modifications, including histone and DNA methylation, histone acetylation and sumoylation, and remodeling of chromatin domains. These findings suggest the hypothesis that character development involves epigenetic processes involving the regulation of gene expression and chromatin modification. LncRNA dysfunction is also often observed in common chronic diseases related to stress and lifestyle regulation, including cancer, cardiovascular disease, neurologic diseases, and immune-mediated diseases. Fortunately, people can create their own health by prudent self-regulation of their lifestyle, including diet, exercise, recreation, and social and occupational activities.

In contrast, the shorter ncRNAs are mostly involved in distinct temporal expression patterns during embryogenesis, acting in specific tissues to regulate expression at a posttranscriptional level. MicroRNAs usually bind to a specific target messenger RNA with a complementary sequence to induce cleavage, degradation, or block translation, and they have crucial roles in epigenesis. Silent-interfering RNA functions in ways similar to miRNAs to mediate posttranscriptional gene silencing as a result of messenger RNA degradation and to induce heterochromatin formation. Piwi-interacting RNAs are so named due to their interaction with the piwi family of proteins. They are involved in chromatin regulation and suppression of transposon activity during embryogenesis. The percentage of ncRNA genes associated with personality is only 5% and does not distinguish the temperament clusters from the character clusters.

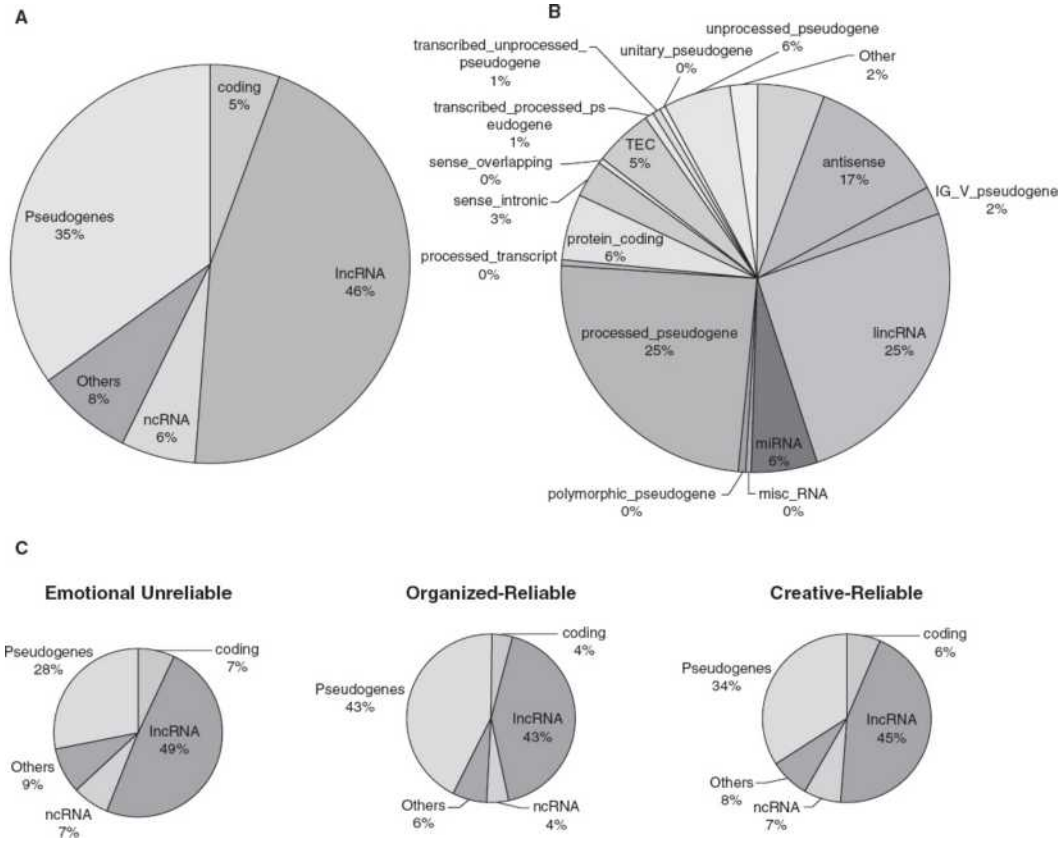

FIGURE 26–4. The types of genes for personality found only in humans. (**A**) Broad gene categories, (**B**) Fine-grained gene categories, and (**C**) Analysis of the genes from (**A**) in the genotypic networks associated with the Emotional-unreliable, Organized-reliable, and Creative-reliable personality networks of modern humans. (Reprinted from Zwir I, Del-Val C, Hintsanen M, et al. Evolution of genetic networks for human creativity. *Mol Psychiatry.* 2021;27:354–376. doi:10.1038/s41380-021-01097-y.)

As shown in Figure 26–3, the distribution of the types of genes associated with character differs from that of other groups. This adds support to findings from longitudinal studies of development and from functional brain imaging that temperament and character are distinct domains of personality with distinct functions in different brain regions. The prominence of regulatory functions for genes associated with personality provides a mechanism for understanding the way learning and memory processes influence personality development as a complex adaptive process. It is clear from the genomic results that personality involves dynamic self-organization that is more or less adaptive depending on both nature and nurture. The convergent findings from neurogenetics and psychosocial development provide a foundation for renewed appreciation of earlier clinical work on personality from diverse fields, including psychodynamics.

Psychodynamic Concept of Character. The psychodynamic concept of character derives from the concept of defense mechanisms. The latter are defined as automatic, unconscious psychological processes (both cognitive and emotional), which protect against anxiety generated by intrapsychic conflicts and external stressors. All defense mechanisms are grouped into three levels, for example, mature (sublimation, anticipation, humor, altruism), neurotic (centered around suppression), and immature (centered around splitting). Psychodynamic concepts (Anna Freud, Otto Fenichel) define mature character traits as residues of previous mature defense mechanisms that have become stable behavior patterns and conscious coping mechanisms. In other words, the mature character reflects one’s capacity to postpone immediate gratification and process internal needs through sublimation, anticipation, altruism, and humor. Behaviors reflecting these particular defense mechanisms correspond partially to the description of Self-Directedness (especially sublimation), Cooperativeness (especially altruism), and Self-Transcendence (especially anticipation and cheerful humor). Thus, psychodynamic theories regarded self-transcendence as a potentially constructive illusion motivated by the demands of the Super-ego to satisfy social requirements. According to psychodynamic theories, the benefits of self-transcendence can be recognized as mature defenses, which develop from unconscious defenses against internal conflicts and later may become conscious coping mechanisms and character traits with mutual benefits for self and others. However, the notion that people are motivated at best by self-interest that may or may not extend to others has never adequately explained the frequent spontaneous display of virtuous behaviors, such as sacrifice for others and other expressions of love, hope, and faith. Today, genetic and neuroimaging research confirms that self-awareness evolved as a third system of human learning in *Homo sapiens* with distinctive molecular and neurobiologic mechanisms that provided humankind with the means to perceive their union with others. As described in the introduction, our inseparability from others is a reality recognized by most people, particularly those who are healthy, happy, kind, responsible, and wise. This ability to be aware of our interconnection with all things involves a perception of a deeper level of reality than is recognized by people who feel the self is separate from other people and things. The failure to recognize our inseparability from others is unfortunate because self-interest is insatiable and ultimately self-defeating; striving for what is unattainable always diminishes health, happiness, and meaning in life.

Psychodynamic theories suggest that the Ego not only protects from but shifts, organizes, and reacts to internal impulses and external stimuli. According to this dualistic perspective, the pattern of the integrative functions attributed to the Ego and the ways in which a person combines various functions to satisfy multiple external and internal pressures constitute a person's character. In other words, the psychodynamic description of Ego-strength corresponds to Self-Directedness, which in the biopsychosocial model of personality is a person's degree of understanding of the self-transcendent virtue of hope. Likewise, in psychodynamic models, Cooperation is motivated by a person seeking mutual benefit to reduce tensions arising from social demands, whereas in the biopsychosocial model, cooperation is a person's degree of understanding of love. Similarly, Self-transcendence is a person's understanding of faith, which Freud considered an illusion, apparently at least in part, because of his own disappointment with the failures of his highly religious father.

Psychodynamic theories describe two forms of character disorders: neurotic character and character neurosis. Neurotic character traits are postulated to derive from neurotic defenses (e.g., suppression, reaction formation, projection, repression, undoing), which have dissociated from their original conflict and have become inflexible, pervasive, and ego-syntonic traits of everyday behavior. Anna Freud called this inflexibility "the armor plating" of character. As extensions of previous conflicts between one's emotions and opposing social pressures, neurotic character traits protect a person from being involved in such situations again. For example, excessive scrupulousness, a frequently observed character trait of obsessive personalities, is a "reaction formation" against their usually strong aggressive impulses. By being rigidly hyperscrupulous, obsessive persons are supposed to protect themselves from conscious experience of aggression and from intrapsychic conflicts that would have been triggered by such an experience. In contrast, according to the biopsychosocial model of personality, such neurotic character traits arise because of inadequate self-actualization (i.e., the development of self-awareness sufficient to integrate a person's habits with their goals and values). Put another way, neurotic character traits are the result of weak self-regulation of temperament by character, which occurs when there has been impaired development of self-awareness due to genetic predisposition and/or environmental influences.

Character neurosis is observed when an inflexible neurotic character trait interferes with healthy parts of the personality. For example, character neurosis is present when excessive cleanness (an ego-syntonic character trait observed with obsessive individuals) frequently interferes with the need to interact freely with others (generated by healthy parts of obsessive personality); instead of being perceived as natural, cleanness becomes so excessive that it is perceived as frustrating. According to the biopsychosocial model of personality, character neurosis occurs when extreme temperament drives inhibit the healthy development of character, as is particularly common with extreme anxiety-proneness (i.e., high Harm Avoidance) and impulsivity-aggressivity (i.e., high Novelty Seeking) in combination with reinforcing rearing experiences, such as parental abuse and neglect. Of note, character neurosis has been included in the *International Classification of Diseases* (ICD)*,* 10th revision, but not in ICD-11, DSM-IV, or -5.

Individual differences in the maturity of defense mechanisms (i.e., normal, neurotic, immature) tend to covary with the severity of psychopathology (i.e., normality, anxiety disorders, PD, respectively). Put another way, the level of a person’s well-being and overall personality development mainly reflects the development of their character (i.e., how high are they on all three character traits of Self-directedness, Cooperativeness, and Self-transcendence). In addition, the subtype of PD depends on their temperament profile, so patients with PD, who in general have immature defenses, also tend to “favor” certain immature mechanisms that express their particular temperament profile and its influence on their character profile, which together, in turn, shape their self-awareness, identity formation, behavioral style, and clinical presentation. These dominant defenses are, for example, the projection for paranoid PD, acting out for antisocial PD, fantasy for schizoid PD, and so forth. Note, however, that in addition to these favorite defenses, PDs also use more general immature defenses that contribute to their irresponsibility, such as their tendency to blame others and act opportunistically in a selfish manner. Reflecting these and similar observations about the importance of defense mechanisms for the overall understanding of deviant personality, the DSM-IV classification enabled clinicians to classify the use of a particular, dominant defense mechanism on Axis II, but the multiaxial system and description of defense mechanisms have been omitted in DSM-5 as psychiatrists operating in managed care settings have increasingly limited the practice to pharmacotherapy without a systematic approach to psychotherapy.

Psyche and Identity

Psychology is literally the study of the psyche, but this word is frequently misunderstood. Psyche refers to a person’s self-aware consciousness, intuitive insight, or spirit. Intuitive insight, such as the inspiration derived from introspection or contemplation, is described by some as silently listening to one’s inner voice, soul, or intuitive Reason. Plato described the process of listening to intuitive reason as recollection or auto-noesis. The contemporary philosopher David Chalmers distinguishes “Mind 1” (i.e., the analytical mind, which is algorithmic and hierarchical in form and uses convergent logic to specific conclusions based on initial assumptions) from “Mind 2” (i.e., the psyche or thought aspect of the soul, which is intuitive and holographic in form and uses intuitive insight and divergent reasoning to explore alternative perspectives and future outcomes as a creative narrative that tolerates ambiguity). Cognitive scientist Endel Tulving showed that the episodic learning system of apes is the foundation for “auto-noetic learning” in modern humans which enables the unique human capacities for self-awareness described in the introduction of this chapter, including human capacities for creativity, narrative art, and language, science, and spirituality. More precisely, in measurable scientific terms, individual variability in the psyche can be measured in terms of differences in a person’s level of intuitive self-awareness, which is observable in terms of the scope of a person’s identity, particularly their degree of self-transcendence. The word “identity” is derived from the Latin *identitas,* which is based on the Latin word *idem* for “same.” The material contents of a person’s body change over time, but a person’s identity has a nonmaterial basis that can be the same throughout the narrative of a person’s life and can even extend beyond the local reality of their self at a particular time and place. Intuitive self-awareness is unique to human beings, but humans do show variation in their level of self-awareness in ways that have a strong influence on susceptibility to PDs or the capacity for wisdom and well-being. In Figure 26–1, the psyche involves the unique human process of symbolic invention, which is based on intuitive self-awareness, leading to the human invention of art, science, and spirituality. The growth of self-awareness is crucial to the development of full coherence of personality, which is manifest as creativity, well-being, and wisdom. The scope of a person’s identity can be quantified in terms of the extent to which a person views their self as a separate localized object or as a self-transcendent being through the process of transpersonal identification.

Psychobiology of the Psyche. Detailed studies of human learning and memory have distinguished procedural, semantic, and episodic memory. As described in relation to temperament, procedural memory underlies associative learning and involves presemantic perceptual processing of information from the physical senses that can operate independently of abstract conceptual and/or volitional processes. In contrast, intuitive learning is based on immediate recognition from a single episode of observation. One type of memory based on immediate recognition is knowledge of facts, which has been called “semantic memory” or “long-term declarative memory,” as discussed in relation to the registration of cognitive schema underlying personality traits. The second type of recognition memory is awareness of one’s own intentions in a spatiotemporal context, which has been called “episodic memory.” In other words, episodic memory involves self-awareness and recall of events in a context that gives personal meaning to the “when” and “where” of life experiences. Initially, this type of recognition memory was defined in terms of materials and tasks, such as intentions (i.e., one’s self in a spatiotemporal context). Subsequently, the concept of semantic memory has been elaborated in terms of intentionality, that is, not only learning of facts but also abstract reasoning, propositions, and intentions about goals and object relationships. Likewise, episodic memory has been refined and elaborated in terms of awareness of one’s self, the sense of subjective time, and a conscious state of self-awareness of the continuity in one’s past, present, and future, which is different from dreaming or imagination. Tulving now describes episodic memory as self-awareness or “autonoetic consciousness,” which is consistent with other descriptions of ordinary human self-awareness as based on immediate recognition by the intuitive senses. Episodic memory is also called “recollection” to distinguish it from factual knowledge that has no personal context in space and time. Tulving notes that there is no evidence that such intuitive self-awareness is present in any animal species except human beings.

Procedural, semantic/intentional, and episodic/self-aware memories can be functionally dissociated from one another. For example, individuals with Parkinson disorder, characterized by striatal lesions, exhibit deficits in procedural learning but not in semantic or episodic memory. Individuals with an amnestic syndrome, characterized by lesions in the medial temporal lobe, have deficits in semantic learning of new facts but not in procedural learning or episodic consciousness. Individuals with amnestic syndrome have anterograde amnesia for new facts but may have no deficit in their immediate sense of self-awareness. Bilateral lesions in the human hippocampus lead to deficits in self-awareness (i.e., episodic consciousness or the intuitive recognition of one’s self in a spatiotemporal context). Episodic memory is subserved by a widely distributed network of cortical and subcortical brain regions that overlaps with, but also extends beyond, the networks subserving other memory systems. Key regions in this network include the hippocampus, regions of the prefrontal cortex (including the frontal poles and medial prefrontal cortex), and the anterior cingulate cortex.

Essentially, the human episodic memory system acts like a mirror that provides spontaneous self-awareness to humans, whereas other primates require the provision of an external mirror to even recognize themselves. This mirroring function depends on hemispheric specialization in the encoding and retrieval of information. The left prefrontal cortex is more involved in encoding episodic memories and retrieval of semantic memories, whereas the right prefrontal cortex is more involved in the retrieval of episodic memories. The episodic retrieval mode is a state of consciousness (in which a person is actively recollecting or remembering their past) that involves the strong activation of sites in the right prefrontal cortex and the weak activation of sites in the left prefrontal cortex and medial anterior cingulate. The ability to recall past events in vivid detail is closely related to the ability to imagine future events in future detail. Hence, the human capacity for recollection and imagination is a component of self-aware narrative learning. People who have been abused or traumatized are often unable to recall events in their life around the time of the trauma and are likely to be unable to imagine their future with sufficient detail to function adaptively in creating a satisfying way of living.

The experimental evidence shows that human beings have an intuitive form of learning and memory as the basis for their unique capacity for self-awareness is now strong, but its significance has yet to be widely appreciated. Current evidence suggests that the hippocampus and other parts of the episodic memory system, such as the prefrontal cortex, are necessary for encoding episodic memories but not for the acquisition of factual knowledge. The hippocampus processes all sensory information available to a person about both one's external and one's internal milieu. Moreover, this pan-sensory information is constantly updated, allowing the registration and recall of ongoing life experiences in a personal context that is unique to each individual. The hippocampus is also known to maintain its plasticity throughout life, including the ongoing generation of new neurons as it adapts to ongoing experience. In fact, genes associated with impaired neurotrophin functions that promote healthy neuronal formation in the hippocampus (e.g., *NTRK3*) are associated with disturbances of self-awareness, as is seen in PDs and the schizophrenias. In contrast, long-term declarative memories, such as factual knowledge and self-reported character traits, are stored in brain networks that show greater stability and less plasticity than the hippocampus.

The plasticity of the self-awareness learning system has important clinical implications for the treatment of PD. Individuals in whom self-awareness is well developed are characterized by a creative character profile in which Self-transcendence is highly developed along with Self-directedness and Cooperativeness. In contrast, individuals in whom the intentional learning system is dominant are characterized by an organized character profile in which Self-directedness and Cooperativeness are highly developed but Self-Transcendence is not. Self-Transcendence is the strongest predictor of the rate of growth in personality in prospective studies, presumably because it is an indicator of both the ability and willingness to change and the ability to evaluate conduct and theories about intangible forces in life, such as love, hope, and faith. In contrast, people who are low in Self-transcendence are less flexible because they are guided by traditions and fixed beliefs. The character strengths of people with organized characters are merely static concepts, which are abstractions from which the spatiotemporal context has been reduced to a factual statement by a fixed choice that eliminates the intentional flexibility inherent in self-aware consciousness. They depend largely on the operation of the intentionality brain network for executive control, symbolization, and storage of facts, which depends at a molecular level on the calcium-second messenger system processing information hierarchically within neurons. Essentially, self-aware consciousness is “living” with many possible outcomes that can be voluntarily influenced, whereas factual knowledge is “dead” or “frozen” like a collapsed quantum wave function. In contrast to the intentionality brain network, the network for creative self-awareness, as described by Cloninger in 2004, depends on distinctive molecular mechanisms that give rise to human consciousness with the quantum-like properties as expected in a scale-free dynamic network in which all components are interdependent and function optimally in coordination. These findings about self-aware consciousness suggest a possible explanation of the importance of intersubjective awareness in the development of self-transcendence and of the substantial resistance to change of character and related cognitive schema when cognitive-behavioral or psychodynamic strategies are used. The plasticity of the episodic memory system and its role in self-awareness also suggests a crucial role for growth in self-awareness as a means of experiential transformation of personality.

Development and Assessment of the Psyche and Identity. Self-awareness is a recently evolved system of learning and memory that appears to be unique to human beings, just as components of the network, such as the prefrontal cortex, are recent evolutionary developments. As expected for a recently evolved function, self-aware learning develops later than procedural or intentional learning. Children younger than 4 years do not yet have a mature, self-aware memory system, so people generally have no direct recollection of their past before 4 years of age. In contrast, basic emotions are present at birth, and self-object differentiation occurs between 18 months and 3 years of age.

Cloninger has observed five distinct levels of identity resulting from varying degrees of intuitive awareness in human beings. There is a hierarchy of levels of awareness that can be measured in terms of what are sometimes called innate human ideas or intuitions about being and human nature. Assessment requires an empathic understanding of the way another person is conscious of being, freedom of will, beauty, truth, and goodness, which provide markers of a hierarchy of levels of awareness. These five aspects of consciousness depend on one’s intuitive awareness of the world. The awareness of facts and intentions are only two of the empirically observable levels of awareness.

For example, some patients with severe PDs complain of “emptiness,” which is a fearful feeling of isolation, separateness, annihilation, or lack of being. Such patients lack a stable awareness of their being, so they are sometimes described as having a borderline level of personality organization. This is characterized by difficulty in sublimation, intolerance of distress, distortions of reality testing, and poor self-acceptance. Their unstable sense of being (i.e., lack of spiritual fullness, identity, and vitality) makes them so emotionally unstable and hopeless that they often mutilate themselves or attempt suicide. About 1% of people are deficient in their intuitive sense of being and experience life with a borderline organization chronically. Another 1% of people experience such disorganization and emptiness intermittently under stress. In contrast, the vast majority of people have a well-developed awareness of being all the time. This level of awareness involves memory of existence with a stable sense of being, that is, without fear of annihilation. This level of awareness is based on the recognition and memory of “facts,” or what has traditionally been called “semantic memory.”

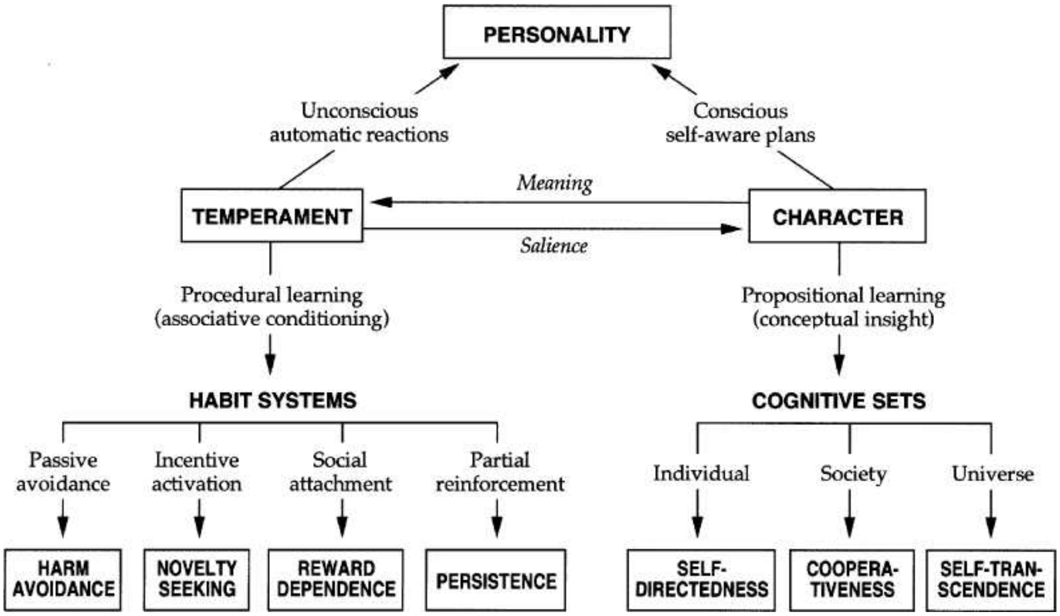
Second, other people usually have hopeful confidence in their being but feel that they are slaves to extrinsic influences and trapped in time like a hell or prison from which they have no means of escape. In other words, such people have a lack of flexibility in their actions or little freedom of will. The lack of awareness of freedom of intention (i.e., will) also distorts the sense of a free flow in time. The lack of consciousness of free will in time has been described as “chronesthesia” (mental time travel) in patients who have brain lesions in their episodic memory system. Even in people with no brain lesions, the lack of awareness of free will can be pervasive. For example, some people are fatalistic materialists and claim that freedom of will is an illusion or something in which they are lacking. Their own intuition contradicts that of humanists and dualists who feel that rational responsibility and freedom of will are what gives human beings their dignity. About 10% of people experience a lack of freedom and the urgency of time commitments to external influences chronically throughout their lives. This corresponds closely to traditional definitions of PD, which involve a lack of freedom or flexibility in adaptive behavior. In contrast, most people have a stable intuitive sense of their freedom and responsibility for their intentions. More generally, this level of awareness involves a person’s awareness of their intentions in a personal spatiotemporal context. This is the second of Tulving’s types of intuition-based types of memories, but it does not exhaust the levels of human awareness.

Third, some people have no esthetic sensibility. That is, some human beings have no intuitive sense of what is lovely or beautiful. Cloninger has observed that those who had attained each level always had an awareness of the lower levels but not the higher levels of consciousness. For example, those with an awareness of beauty also had an awareness of being, freedom, but not necessarily an awareness of truth or goodness. In other words, these indicators of consciousness define a hierarchy of levels of awareness. It is shocking to recognize that some patients with PDs have no recollection at any time in their lives of feeling a sense of wonder and admiration for the beauty of any poem, painting, or nature scenes! Try to understand what that means for the quality of their lives. When such unaware individuals see a rainbow, they do not feel it is beautiful or wonderful! They just see physical colors and shapes with no conscious recognition of beauty. The complete absence of any sense of love and beauty is rarely acknowledged, occurring in only about 3% of individuals, but many more show little intensity in their appreciation of beauty. Although they know what opinions are fashionable, it has little or no impact on their ordinary awareness. Individuals with an unstable sense of beauty are consequently unstable in their capacity for love and emotional intimacy in relationships. Approximately half of marriages in the United States end in divorce, which is an objective indicator of instability in the sense of what is beautiful and loved. In contrast, the stable intuitive sense of what is beautiful and loved is characteristic of the other half of the general population, who have sometimes been designated as “romantics.” In particular, esthetic sensitivity is a highly developed intuitive sense in romantic poets and novelists, such as Emerson and Thoreau, and in romantic musicians, such as Schubert.

Fourth, still other individuals have a sense of being, freedom, and beauty at least some times in their lives but never have any intuition of absolute truth. This is typical of individuals who describe themselves as pragmatists or objectivists. Such individuals also are usually agnostic or atheists because they have no intuition of their participation in a unity of consciousness, which gives rise to faith. About 10% of individuals in the United States are atheists or agnostics, which is consistent with recent nationwide Gallup polls. According to Gallup polls (2017), about 9 of 10 (87%) Americans believe in God, but the majority do not feel that institutional religions are adequately inspiring and satisfying their spiritual needs. Eight percent of Americans do not believe in God but believe in a universal spirit or higher power. Only 5% of people are atheists who also deny belief in a universal spirit or higher power. However, it is important to note that many people who describe themselves as atheists or agnostics actually have a well-developed spiritual sensitivity, as has been described by David Hay. In fact, some atheists may be more spiritual in their dedication to truth and tolerance than people who regularly attend religious services out of custom and convention.

Individuals who have attained each level usually have had an awareness of the lower levels but not the higher levels of consciousness. For example, individuals with a sense of emptiness also lacked awareness of freedom, beauty, truth, and goodness. Those with an awareness of truth also had an awareness of being, freedom, and beauty but not necessarily an awareness of goodness. Hence, awareness of truth is an intuitive sense that is well developed in elevated levels of consciousness. The intuitive sense of truth is prominent in many scientists, such as Teilhard de Chardin and Carl Rogers. It is even more fully developed in highly self-aware sages, such as Hegel, Leonardo da Vinci, and Gandhi, who viewed their lives as experiments in truth.

Fifth, still other individuals may have had a sense of being, freedom, beauty, and truth at times in their lives but had never had any intuition (i.e., direct awareness) of the intrinsic goodness of all things despite the perversions and corruption that exist in the world. Unfortunately, this group includes nearly everyone at times when they wonder about the existence and nature of evil or seek retribution and revenge against other human beings who threaten or attack us or perhaps only frustrate us. Deep awareness of the universal unity of being and consciousness is required to love one's enemies. The intuitive sense of goodness is well developed only rarely. There is a partial awareness of it in individuals who are highly developed in all three character traits, including Self-Transcendence, such as the American transcendentalists such as Emerson and Thoreau. However, a well-developed awareness of goodness occurs only rarely, as in wise people such as Plato and Gandhi.



PERSONALITY
Unconscious automatic reactions
Conscious self-aware plans

COOPERA-TIVENESS
SELF-TRAN-SCENDENCE

FIGURE 26–5. Personality: An integrated psychobiological schema.

Finally, it is important for clinicians to realize that character development is modular and stepwise, and there can be blind spots or blockages in any particular module. As a result, there are infrequent exceptions to the rule that high levels of awareness imply awareness at all the lower levels. Such exceptions are particularly striking in high-functioning patients, such as alcoholic physicians and other professionals. Such patients may have mature character development overall but have specific blind spots in their insight and judgment that lead to serious impairment in particular aspects of their lives, such as romantic relationships or various forms of impulse control.

PERSONALITY: AN INTEGRATED VIEW

Recent reports about complex and fundamental processes underlying neurophysiology, development, and phenomenology of personality provide powerful guidelines for the formulation of a comprehensive biopsychosocial model of personality as the coherent organization of the human body, mind, and spirit. The model integrates earlier phenotypic observations about behavior with contemporary concepts based on neuroimaging, the biology of behavior, genetics, psychometric advances, and nonlinear modeling of normal and deviant personality development. Personality is conceptualized as a complex adaptive system involving a multidimensional interaction among temperament, character, and psyche. The coherent maturation of personality requires awareness of the natural unity of being, which, in turn, depends on the interplay of three systems of learning and memory for behavioral conditioning of habits and skills, intentional learning of facts, goals, and logical propositions, and self-aware insight and appraisal of values and theories (Fig. 26–5).

Through the interaction of temperament and character, different aspects of meta-cognition of the self and the external world modify the significance and the salience of sensory percepts and affects regulated by temperament and vice versa. In other words, temperament regulates what one notices and, in turn, character modifies its meaning so that the salience and significance of all experience depend on both one's temperament and character. In turn, the development of character is derivative of individual differences in intuitive self-awareness. Essentially, personality development depends on the joint interactions among three systems of learning and memory. These are the systems for behavioral conditioning, intentionality, and self-awareness, which are related to temperament, character, and identity, respectively. Reliable measures of the functioning of these three systems are provided by temperament (procedural learning of emotional drives), Self-Directedness and Cooperativeness (intentional self-control of goals and object relationships), and Self-Transcendence (self-aware learning in autobiographical memory with a creative imagination and theory of mind). The least plasticity is in temperament (behavioral conditioning), and the most plasticity is in self-awareness, with intentionality intermediate to the other two in its malleability.

Consequently, treatment efficacy depends substantially on whether treatment is focused on temperament, character, or identity. Somatic therapies, medications, and behavioral conditioning target the temperament, which usually changes little beyond specifically conditioned situations. Cognitive and psychodynamic approaches seldom eliminate or transform maladaptive cognitive schemas (i.e., transform intentional goals and propositions) but may improve the management of conflicts by means of prolonged treatment of more than a year. Only treatment focused on intuitive awareness is likely to lead to an actual cure of PD by the transformation of the level of intuitive awareness (i.e., insight and judgment). Randomized controlled trials now do show the effectiveness of such triple-process approaches.

Any effective treatment has to allow the patient to be ready to see the world more coherently. Extreme temperament traits make PD patients inflexible, biased, and reactive. These “armor-like” features make it difficult for these patients to elevate their self-awareness so that they can see or feel or intuitively recognize the world of beauty and truth that seems “hidden” to them. Everyone has become able to recognize how beautiful the truth is only after they are able to achieve a level of personal acceptance. Medication and cognitive therapies can help a person to be “ready” for higher levels of maturity, but the transformation always involves a change in perspective. Therapists must be flexible and alert to opportunities to help patients see through the fog of their fears and other negative emotions, which cloud their perspective. The key to change is often quite unique and unexpected. Accordingly, there is no recipe or algorithm by which individuals always progress, and effective therapy requires ingenuity and flexibility because of the uniqueness of each person’s strengths and weaknesses.

ESSENTIALS OF PERSONALITY ASSESSMENT IN CLINICAL PRACTICE

The assessment of personality can be made during routine assessment combining information from mental status and the lifetime psychiatric history. Integrating this information means that the clinician must recognize and understand the invariance of the organization of human thought regardless of timescale: mental status observations span milliseconds (e.g., a transient smile, fear, or anger) to minutes (e.g., perceptual awareness, fluidity of speech, resourcefulness, and speed in problem solving) whereas the lifetime history spans months (e.g., episodes of depression, gambling, substance abuse) to decades (e.g., repeated divorces, achievements). Human thought is dynamic with an average of 10 different thoughts per second, involving sudden shifts in attention, emotion, and intention, but it varies in ways that can also be observed to develop over the entire lifespan of the same individual. To be able to describe and understand this variability coherently, it is helpful for a clinician to have an integrated model of the structure of thought and personality.

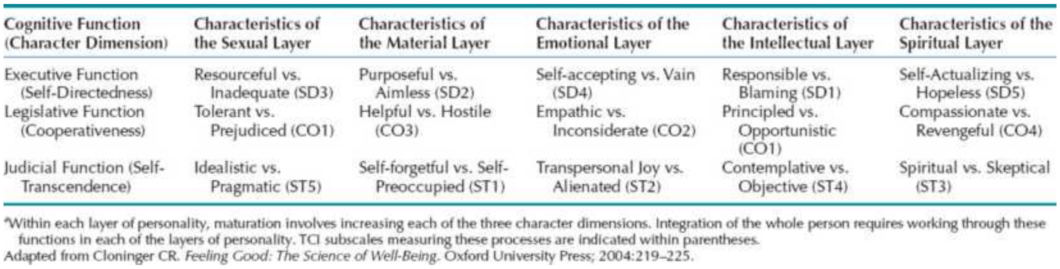
Human personality has five layers or “planes of being,” according to Cloninger. The five layers of personality are concerned with human adaptations in situations that are perceived to be predominantly concerned with reproduction and sexuality (“sexual plane”), practical everyday activities concerned with power and possessions (“material plane”), emotional bonds and social attachments (“emotional plane”), communication and culture (“intellectual plane”), and understanding what is beyond individual human existence (“spiritual plane”). The brain systems that make it possible for human beings to adopt these different perspectives have evolved in a hierarchy of discrete steps over time to allow the survival of progressively more flexible, aware, and creative organisms.

The development of well-being and the regulation of potential conflicts among emotional drives in self-aware consciousness involves three branches of mental self-government. These branches of self-government correspond to the higher cognitive processes related to the three character traits and should be systematically assessed during the mental status examination. The assessment of insight and judgment is often trivialized to a subjective judgment about whether patients agree with their doctor ("insight") and do what they are told to do ("judgment"). It is more useful to evaluate insight as a combination of reasoning ability (self-directedness) and intuition (self-transcendence), which corresponds well to concepts of insight as rational intuition that date back at least to the writings of Plato. Judgment has come to mean something like the legislative function measured by Cooperativeness, providing a capacity for empathy, teamwork, and principled action. However, the rating of these processes can be made much more informative and precise by recognizing how the three character traits are expressed in different situations. Each of these three cognitive functions has modules for adapting to each type of situation or layer of personality, which can be measured reliably by specific facets of character.

The three branches of mental self-government and their components are summarized in Table 26–12, along with the specific subscales of the Temperament and Character Inventory (TCI) designed to measure these functions. Self-Directedness in the TCI measures the executive functions, which can be considered the strength component of insight. It is expressed in various situations, including a person being self-directed in the sexual plane (i.e., resourceful), in the material plane (i.e., purposeful), in the emotional plane (i.e., self-accepting), in the intellectual plane (i.e., responsible), and in the spiritual plane (i.e., self-actualizing with few bad habits that interfere with achieving one's goals). On mental status examination, a person may be impartial and realistic in their thinking, high in self-esteem, and resourceful and far-sighted in actualizing their plans if they are highly self-directed, or they may be emotionally vulnerable, biased and unrealistic in their thinking, low in self-esteem, and short-sighted in planning. Remember that the rating of this one characteristic (executive functioning expressed as self-directedness) reveals more about the level of the person's maturity, their vulnerability to psychopathology, and their prognosis for recovery with a positive quality of life than any other feature of the mental status. Self-directedness is the expression of a life guided by a sense of hope that allows a realistic acceptance of reality as a path to understanding the wonders and mysteries of life, even if they appear inconsistent with past expectations. Self-directedness is not a fixed trait—it can be temporarily reduced during stress, trauma, intoxication, or psychosis, and it can be enhanced by psychotherapy or life experiences such as opportunities to gain in self-directedness by one's accomplishments from responsible work. Everyone can grow in self-directedness under appropriate therapeutic conditions, such as reduced stress, nonviolence, and sobriety, especially when encouraged by the hope and compassion of others.

Cooperativeness measures judgment as the legislative function, which involves making rules that allow people to get along in a reasonable and flexible manner with one another in each plane of their life. Cooperativeness can be recognized in the sexual plane as tolerance instead of prejudice, in the material plane as being helpful instead of hostile, in the emotional plane as empathy instead of self-centeredness, in the intellectual plane as being principled instead of opportunistic, and in the spiritual plane as a sense of compassion and fairness instead of vengefulness. In brief, good judgment is shown by a person's flexibility and ability to get along with others with values guided by compassion and principle. Poor judgment is shown by prejudice, lack of impulse control, insecure or hostile attachments, difficulty with teamwork, and opportunism. Comparison of a person's interaction during mental status examination with their life history is important to understand the range of cooperativeness they have demonstrated at different times during their life. For example, a person who is usually cooperative may temporarily become inflexible and hostile under stress or the aftermath of violent trauma. Alternatively, a person who has been uncooperative in the past may develop better judgment. A person may also have a blind spot in their awareness that elicits uncooperativeness in a recurrent but specific type of situation but allows good judgment in most other situations.

Table 26–12.
Descriptions of Three Branches of Mental Self-Government (Executive, Legislative, and Judicial Cognitive Functions) That Regulate the Emotional Drives Relevant to Each of the Five Layers of Human Personality, Which Are Defined by the Predominant Focus of the Person's Perspective in a Situation[a]



Cognitive Function (Character Dimension)	Characteristics of the Sexual Layer	Characteristics of the Material Layer	Characteristics of the Emotional Layer	Characteristics of the Intellectual Layer	Characteristics of the Spiritual Layer
Executive Function (Self-Directedness)	Resourceful vs. Inadequate (SD3)	Purposeful vs. Aimless (SD2)	Self-accepting vs. Vain (SD4)	Responsible vs. Blaming (SD1)	Self-Actualizing vs. Hopeless (SD5)
Legislative Function (Cooperativeness)	Tolerant vs. Prejudiced (CO1)	Helpful vs. Hostile (CO3)	Empathic vs. Inconsiderate (CO2)	Principled vs. Opportunistic (CO1)	Compassionate vs. Revengeful (CO4)
Judicial Function (Self-Transcendence)	Idealistic vs. Pragmatic (ST5)	Self-forgetful vs. Self-Preoccupied (ST1)	Transpersonal Joy vs. Alienated (ST2)	Contemplative vs. Objective (ST4)	Spiritual vs. Skeptical (ST3)

[a] Within each layer of personality, maturation involves increasing each of the three character dimensions. Integration of the whole person requires working through these functions in each of the layers of personality. TCI subscales measuring these processes are indicated within parentheses.
Adapted from Cloninger CR. *Feeling Good: The Science of Well-Being*. Oxford University Press; 2004:219–225.

Self-Transcendence measures the depth component of insight. Depth of insight allows people to know intuitively when legislative rules apply in a particular situation. The depth of a person's insight is shown in the sexual plane by a person's being idealistic rather than selfishly pragmatic. Depth of insight is shown in the material plane by being self-forgetfully absorbed in action rather than self-preoccupied. In the emotional plane, insight is shown by awareness of one's transpersonal connections with nature and other people, which leads to a sense of abundance, joyful exuberance, and being altruistic and gracious. In the intellectual plane, depth of insight is shown by being contemplative rather than materialistically objective. In the spiritual plane, insight is shown by a sense of connectedness to what is divine or beyond human existence, expressed as faith or spiritual acceptance rather than skepticism or nominalism. In general, poor depth of insight is shown by the shallowness of awareness or magical ideation, whereas the depth of insight is shown by wisdom, creativity, faith, and depth of understanding. In most people, the depth of insight is indicated by the frequency of peak experiences of transpersonal union, inseparable connectedness with nature, or oceanic feelings. However, reports of such peak experiences are sometimes the product of magical (schizotypal) thinking in people who are very low in self-directedness. Hence, it is important to evaluate both the strength and depth components of insight (i.e., both self-directedness and self-transcendence).

All personality modules involve person-by-situation interactions that are regulated by a set of dynamical nonlinear systems, which allows human beings to be purposeful, flexible, and self-aware in their adaptation to life. *Human personality is not adequately characterized as a set of linear traits because the components of personality are nonlinear in their functional effects and relationships with one another.* Human thought involves the frequent rapid adaptation of a person to different situations or different perspectives on the same experience. The connections between different brain modules change suddenly and synchronously with changes in thought.

The full three-dimensional structure of personality can be visualized as a three-dimensional spiral with five planes and increasing in height, width, and depth from the sexual to the spiritual plane. The height of the spiral indicates a person’s strength of insight, as measured by their level of TCI Self-Directedness, which indicates a person’s strength to face and adapt to reality rather than to blame, deny, or repress unpleasant facts. The width of the spiral indicates a person’s broadness of social concern and flexibility of judgment, as measured by their level of TCI Cooperativeness. The depth of the spiral indicates a person’s depth or shallowness of insight, as measured by their level of TCI Self-Transcendence. Essentially, a person’s thoughts can shift rapidly throughout their possible range, spiraling down with increasing negative emotions and other indicators of ill health when stressed (e.g., preoccupied with fears, threats, or desires) or spiraling up with increasing positive emotions and other indicators of well-being when calm and secure (e.g., feeling hopeful, kind, and aware). A psychiatrist is often presented with a patient in a state of distress in which their thoughts have fallen to a low point in the range. The first step in treatment is to create conditions that allow the patient’s thoughts to ascend in the spiral of self-aware consciousness through validation, encouragement, medication, and mental or breathing exercises that allow a person to regain their more hopeful, kind, and coherent perspective toward life. Later work can help understand and reduce their vulnerabilities for relapse and recurrence.

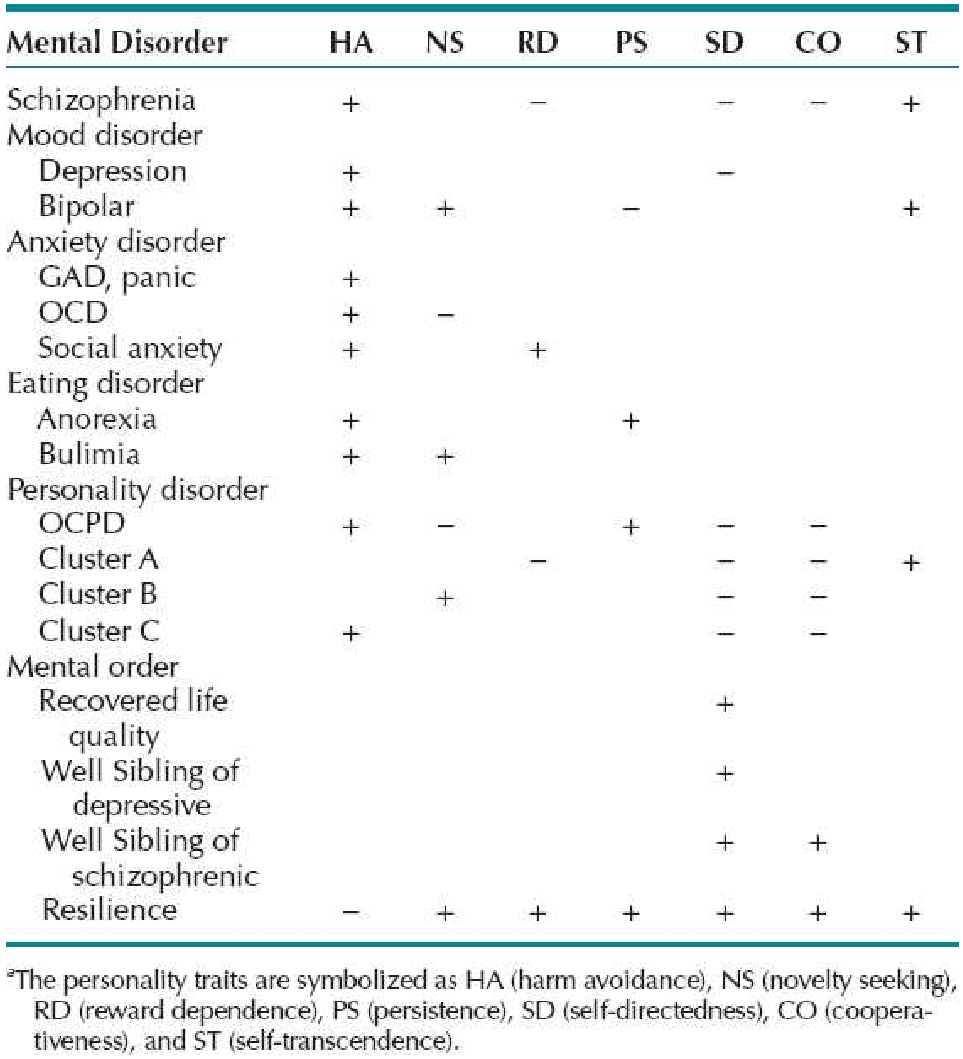
Although human thought is highly dynamic with a wide range, one can use averages or modes of one's thoughts and relationships as central indicators of states of being that are metastable, as is typical of equilibrium states in nonlinear dynamical systems. Frequent metastable states of being are often described as personality traits, even though they are neither fixed nor linear in their functions and relationships. Accordingly, personality is a way of describing the dynamic processes that occur within the person to shape and adapt to life experiences by learning and planning. The maturation and integration of human personality involves one's growing in self-awareness through experiences across this wide range of situations.

As a result, personality is a complex expression of nonlinear interactions among a whole hierarchy of learning systems that develop over time as a complex adaptive process. Each personality module has three aspects, each regulated by dissociable but overlapping systems of learning and memory: a somatic or emotional aspect regulated by learning of habits and skills, a cognitive aspect regulated by learning of facts and propositions, and a spiritual aspect regulated by self-aware learning of one's continuity with and participation in a whole greater than oneself. These three systems can be dissociated but normally interact through their extensive interconnections. For example, a person can know how to do something (using procedural memory) but not know the fact that he knows the skill (a deficit in semantic memory). A person can know a particular fact and report it to others (using semantic memory) but not have a memory of when and where they learned the fact (a deficit in episodic memory). The systems evolve and mature in sequence but operate simultaneously from early in childhood. As a result, the same symptom (e.g., feeling rejected) can be the result of different vulnerabilities (e.g., temperaments with high Reward Dependence, character with low Cooperativeness, poor intrapsychic integration leading to low well-being). Therefore, the effective clinician must look beyond presenting symptoms to understand and treat the underlying processes that produce symptoms, which is not possible with categorical diagnoses or multidimensional systems designed to compare and judge one person against another. Nevertheless, it is possible to use information about clinical syndromes to help identify the underlying processes that are most likely.

Table 26–13 lists the personality traits that are most consistently associated with different clinical disorders and states of mental health. This is not meant to be an exhaustive listing of all the personality correlates of different mental disorders but only the traits that are so strongly related to different disorders that a clinician can use the information in the differential diagnostic process. For example, high Harm Avoidance is commonly associated with most forms of psychopathology, but it has a particularly strong relationship as a cause of mood and anxiety disorders.

Therefore, high Harm Avoidance should be suspected as a predisposing trait in mood and anxiety disorders. The presence of Harm Avoidance can be quickly evaluated by inquiring about child and adolescent traits such as being a worrier, pessimist, or shy. Likewise, high Novelty Seeking should be suspected if a person is alcoholic, drug abuser, gambler, or bulimic. Novelty Seeking can be quickly evaluated by inquiring about a person having a quick temper in their youth, being impulsive, extravagant, or rule-breaking, instead of slow-tempered and liking order and structure in what they do. On the contrary, mature character development confers well-being and resilience to psychopathology. In addition, positive character development facilitates recovery from mental illness, promoting the development of a sense of coherence, personal mastery, self-esteem, and life satisfaction. Thus, the distinction between temperament traits, which are value-neutral, and character traits, whose development can facilitate recovery and well-being, provides a perspective that is encouraging and not pejorative.

Table 26–13.
Personality Traits[a] That Are Highly Likely to Be High (+) or Low (–) in Different Mental Disorders and States of Mental Health



Mental Disorder	HA	NS	RD	PS	SD	CO	ST
Schizophrenia	+		−		−	−	+
Mood disorder							
Depression	+				−		
Bipolar	+	+		−			+
Anxiety disorder							
GAD, panic	+						
OCD	+	−					
Social anxiety	+		+				
Eating disorder							
Anorexia	+			+			
Bulimia	+	+					
Personality disorder							
OCPD	+	−		+	−	−	
Cluster A			−		−	−	+
Cluster B		+			−	−	
Cluster C	+				−	−	
Mental order							
Recovered life quality					+		
Well Sibling of depressive					+		
Well Sibling of schizophrenic					+	+	
Resilience	−	+	+	+	+	+	+

[a] The personality traits are symbolized as HA (harm avoidance), NS (novelty seeking), RD (reward dependence), PS (persistence), SD (self-directedness), CO (cooperativeness), and ST (self-transcendence).

CONCEPTUAL AND PSYCHOMETRIC ISSUES

Personality Traits: Person versus Situation Debate

Personality traits are neuropsychic structures with the capacity to render many stimuli functionally equivalent and to initiate and guide equivalent (consistent) forms of adaptive and expressive behavior. Accordingly, the DSM defines personality traits as “enduring patterns of perceiving, relating to, and thinking about oneself and the environment,” that is, other people and the world as a whole. The major value of personality traits, therefore, lies in their usefulness in identifying predictable regularities in an individual’s behavior.

The stability of personality traits in time and across situations has been the central issue in personality theory for decades, as it bears direct relevance to the question of whether internal dispositions or external situations determine behavior. The "person vs. situation" debate was initiated in the early 1900s by two groups of scientists ("situationists" vs. "personologists"); the former viewed behavior as highly situationally specific, the latter as centrally organized and purposive. As noted by Epstein and O'Brien, the dilemma remained unresolved for decades because it was not realized that behavior can be situationally specific at the item level and cross-situationally general at the aggregate level. Single items of behavior have limited reliability and generality. They must be aggregated over situations and occasions in order to reveal broad and stable traits, which allow moderately accurate predictions of behavior tendencies (without having to specify the eliciting situations) but only weak predictions of behavioral acts in particular situations.

On the contrary, global personality traits also do not explain behavior completely because people do not exhibit unmodulated consistencies in behavior across time and situations (complete invariance in behavior is associated more with psychopathology than with normality). Biogenetic factors influence how an individual adapts to experience, and the latter modifies adaptive tendencies. Hence, personality traits are not fixed. This current understanding of traits differs from the conservative one of 25 years ago. The emerging consensus is an interactionist position allowing room for both situational (external) and dispositional (internal) determinants of behavior in a variety of complex combinations, as described in Tables 26–11 and 26–12 for temperament and character. Fortunately, it is now possible to specify facets of personality traits that are relevant to particular situations and also to aggregate these facets into aggregate scales that are moderately predictive across a broad range of situations. In comparisons among many popular personality models, the TCI predicts behavior and clinical disorders as well or better than other models.

Phenotypic and Developmental Trait Personality Models

The major difficulty in relating observed variation in personality to its underlying biologic processes is that the observed phenotypic structure that distinguishes one person from another differs from the underlying psychobiological organization of adaptive processes that occur within the individual. Factor analysis describes only the differences between people, not the number or content of the processes that occur within individuals as they learn to adapt in time. Hence, the *phenotypic trait personality models,* which are usually factor analytically derived (e.g., Eysenck's tridimensional model, Costa and McCrae's Five-Factor Model), account for much of the observed phenotypic variance but may not correspond to the underlying intrapsychic processes. For example, Neuroticism is a composite of both high Harm Avoidance and low Self-Directedness. However, Harm Avoidance and Self-Directedness have unique genetic determinants and are regulated by different brain circuits. For example, Harm Avoidance, and not Self-Directedness, is moderately correlated with Mismatch Negativity in evoked potentials, which is a measure of behavioral inhibition related to the orienting response, automatic attention, and early unconscious sensory processing. Furthermore, Self-Directedness, but not Harm Avoidance, is strongly correlated with activity with the late-evoked potential P300 and with activation of the medial prefrontal cortex in fMRI studies during executive tasks. This double dissociation of Harm Avoidance and Self-Directedness with early- and late-occurring evoked potentials is consistent with the phylogenetic history of Harm Avoidance evolving early and Self-Directedness evolving late.

In contrast, *developmental trait personality models* take into account both the underlying biologic dispositions to observable behaviors and individual differences in responses to experience during personality development. The most recognized dimensional models are those of Sjobring, Zuckerman, and Cloninger. Despite some limitations, Sjobring's developmental model in the late 1940s is a heuristic attempt to take personality research beyond the level of phenotypic observations and factor analysis. The model defines three dimensions of latent variation predisposing to personality: "validity" (i.e., the degree of energy available in adaptation to experience), "solidity" (the consistency of adaptation), and "stability" (referring to the maximum potential of a person to develop skillful habits in adapting to routine). These three genetic dispositions were postulated to be independent of one another and from the factor of general intelligence (referred to as "capacity") and also to define one's susceptibility to behavior disorders. Validity is similar in description to low Harm Avoidance, Solidity to low Novelty Seeking, and Stability to low Reward Dependence.

Personality has often been described in terms of a linear sequence of qualitatively discrete developmental stages and structural types. However, the frequent occurrence of heterotypic individuals with intermediate or mixed features calls into question the basic assumption that personality structures are limited to a finite number of types that are qualitatively discrete and homogeneous. Likewise, it is becoming increasingly clear that there is not only variation in the rate and direction of personality development as a whole but also asynchrony and inconsistency among its major components that are reorganized through time. The following section outlines a more general nonlinear quantitative theory of personality development that does not make the restrictive assumptions about a finite number of qualitatively discrete structural types.

PERSONALITY DEVELOPMENT: A SELF-ORGANIZING BIOPSYCHOSOCIAL COMPLEX

The development of normal and abnormal personality traits can be quantified as a complex dynamic system that is self-organizing and partly molded by familial and sociocultural influences. In order to formulate a realistic model, Svrakic and colleagues (1996) had to allow for the reciprocal interactions among multiple and etiologically distinct components of personality that account for its complex patterns of development across a person's lifespan. This biopsychosocial model also accounts for the frequent, but not invariant, development of stage-like periods of moderately stable personality configurations (similar to personality types) punctuated by abrupt transitions in which there is structural reorganization and emergence of qualitatively new features. The model is based on a sophisticated mathematical framework that has been implemented and tested with prospective empirical data. More recently, the developmental interactions among temperament, character, and identity in terms of interactions among the systems of learning for behavioral conditioning, intentionality, and self-awareness have been tested and interpreted.

The central ideas behind this model are the following:

- Personality is a multidimensional dynamical system comprising more elementary operating components (traits) that are organized in an interdependent way critical to carrying out a particular function. Such a system is characterized by particular rules of operation, for example, the principles of associative learning within the temperament function, long-term intentional learning within the system for self-control of goals and relationships, and the development of insight by self-awareness in identity formation. The satisfaction of such multiple constraints results in nonlinear dynamics, which is characteristic of all systems involving growth and development in biology, neuroscience, psychology, and sociology. Such multidimensional dynamical systems are usually called complex adaptive systems.
- The correlations observed among multiple personality traits can be used to explain the spontaneous organization of stable multidimensional configurations (i.e., personality types); these types develop in a stage-like fashion with successive periods of prolonged stability punctuated by rapid transitions. However, the progression of each individual is unique because differences in intuitive awareness result in substantial variability that is unique to each individual.
- The model accounts for functional interactions among multiple types of influence, including genetic factors, family environment, sociocultural norms, and experiences unique to each individual.

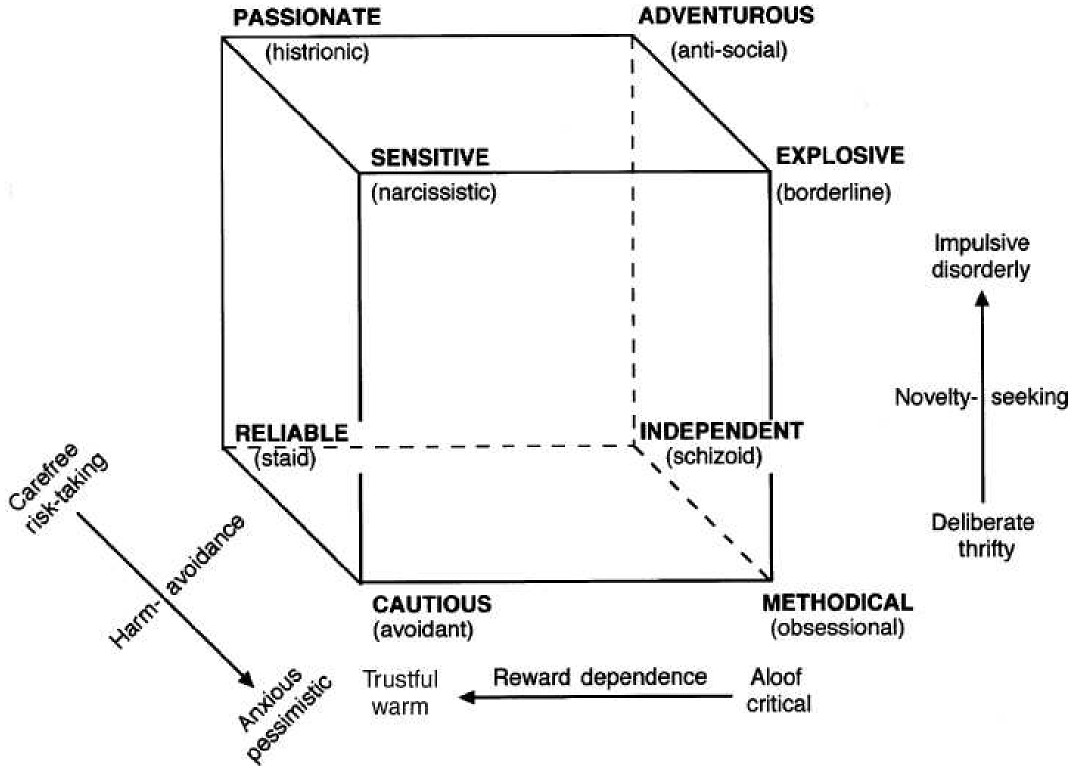
- Based on the specified basic differences between temperament, character, and identity (Table 26–10), this model takes into account all aspects of information processing, from associative conditioning of habits and skills to enculturation about goals and values within a unique biopsychosocial context.

Personality development is presented as a walk on an adaptive (or fitness) landscape with two or more hills (representing high adaptive values) separated by valleys (representing low adaptive values). Fitness is defined as the ability to produce a change in personality. In general, a complex system subjected to constraints responds to these constraints by optimizing fitness, that is, by adaptive changes in personality. As change in personality is motivated by optimization of fitness, people will most likely and most rapidly move in the direction of the greatest increase in adaptive value (i.e., the nearest hill). Once they have reached the peak of the hill, they will stay there for a relatively long time because they would first have to decrease fitness (i.e., descend into the valley) in order to find a hill with a higher peak (i.e., better adaptation). Such adaptive development is called U-shaped.

As noted, temperament and character traits are etiologically distinct but functionally related. Such an interactive system has the property of being self-organizing as a result of the collective dynamics among its multiple components. In other words, the organism is spontaneously driven to find patterns of behavior that result in the coherence of all information about both the external and the internal milieu. For example, Harm Avoidance interacts with both Novelty Seeking and Reward Dependence, inhibiting approach to novel stimuli and inhibiting social attachments by increasing fear of the unfamiliar and sensitivity to social criticism. Accordingly, consistent negative correlations of Harm Avoidance with Novelty Seeking and Reward Dependence have been found. In contrast, Novelty Seeking and Reward Dependence are positively synergistic, facilitating sociability and seeking social approval. Such interactions influence the stability of each of the eight possible multidimensional configurations or “profiles” of temperament traits (Fig. 26–6), making some more stable than others.

In the fitness landscape, the valleys (or the adaptive minima) are unstable because even small perturbations, such as random events, will drive the system away from these points of the lowest fitness. In contrast, hills (i.e., adaptive maxima) are stable because they act as “attractors” for all lower points in the neighborhood. Consequently, personality interactions tend to self-organize into such an attractor state and to remain in that configuration in the absence of external pressure or maturational processes. For the understanding of both the chronicity and treatment resistance of PDs, it is of critical importance to realize that a particular personality configuration may be highly stable, even though it may not be the most adaptive behavior possible for that individual (to be discussed).

We are mainly concerned with patterns of change of character traits as a function of relatively stable temperament traits and variation in the level of self-awareness, as discussed later. The three character traits interact to produce eight possible character configurations or profiles (Fig. 26–7).



PASSIONATE

critical

FIGURE 26–6. Temperament configurations.

Any change in these character configurations can be predicted from the initial temperament configuration taking into account temperament–character interactions and the effects of sociocultural norms, random events unique to the individual, social learning within the family, and genetic factors. However, whether there is change depends on self-awareness, which is unique to each individual and unpredictable, that is, underdetermined or free. All these sources of individual differences influence the likelihood for different stable character configurations in the outcome. The sociocultural norms can be additionally accounted for as the systematic bias in development associated with demographic variables, such as subculture, gender, race, age, and occupation. These norms and social education in the family create environments that are supportive or oppressive of specific character development. With all this taken into account, it turns out that a single initial temperament configuration may lead to several different stable character configurations; this aspect of development is referred to as multifinality. These results are graphically represented in

Figures 26–8 through 26–10, with different initial temperament configurations and their possible character outcomes.

Three dimensions of character (Self-Directedness—SD, Cooperativeness—CO, and Self-Transcendence—ST) are drawn along three orthogonal axes, and each character configuration is represented by a point in this abstract space. Eight possible high–low combinations of three character dimensions are represented by the corners of the cube. Observe that certain temperament types may and do give rise to several possible stable character outcomes, each with a certain probability, a feature characteristic of nonlinear systems. The size of the bulging at a particular character configuration is proportional to the probability of that outcome. Figures 26–8 through 26–10 illustrate this for adventurous (Hi NS, Lo HA, Lo RD), explosive (Hi NS, Hi HA, Lo RD), and sensitive (Hi NS, Hi HA, Hi RD) temperament types. Similar results can be obtained for the remaining five temperament configurations.

Individuals are born with one temperament profile with several possible character outcomes. This multifinality reflects the fact that the fitness landscape in personality development has both objective and subjective components. The sense of identity, feelings, and intentions unique to the individual do influence the evaluation of the “objectively” worthwhile goals and values. The observed discrepancies between the natural directions influenced by antecedent temperament traits and actually achieved character configurations point to the importance of external events such as social learning and random fluctuations in the final character outcome.

hostile

FIGURE 26–7. Character configurations.

As a result of the presence of points of high- and low-adaptive values in the fitness landscape, personality development is characterized by periods of relative stability alternating with more rapid transitions to new adaptive levels. The subscale structure of the TCI was formulated to specify character in terms of 15 component steps of its development, as shown in Table 26–14.

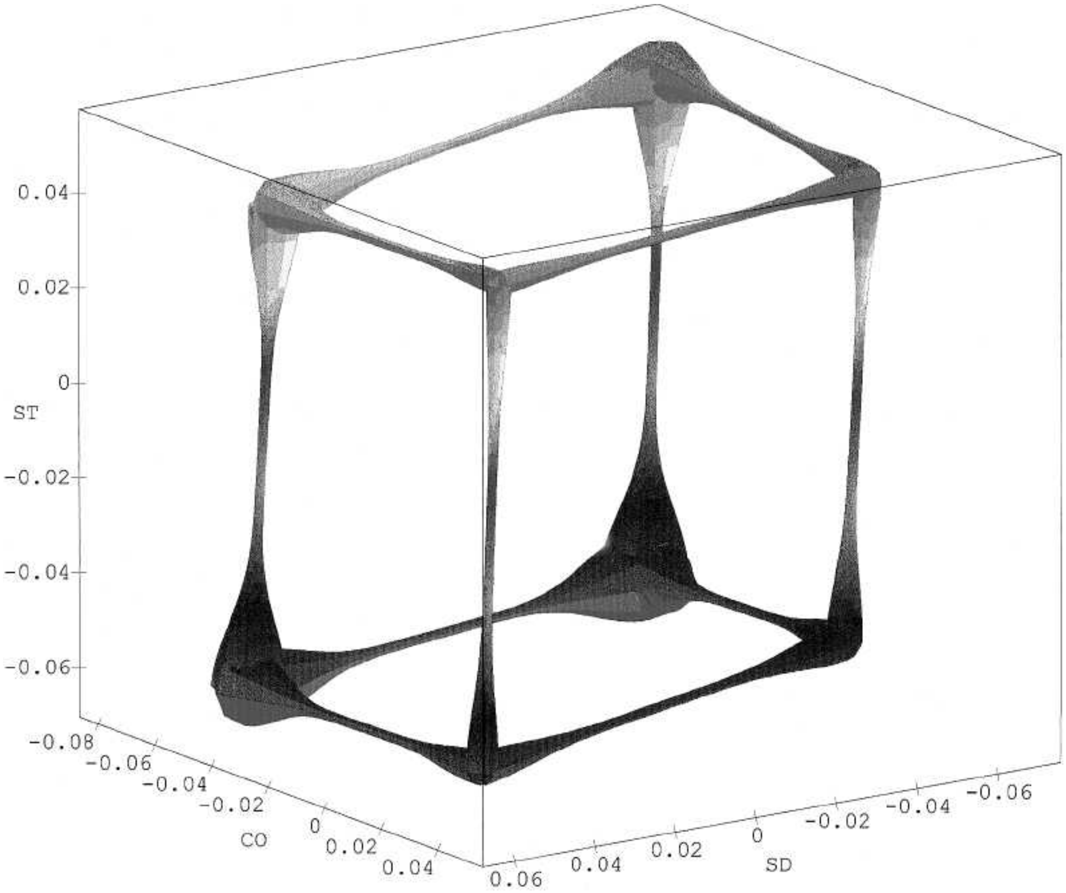

FIGURE 26–8. Most probable character outcomes for the adventurous antecedent temperament traits. CO, cooperativeness; SD, self-directedness; ST, self-transcendence.

The 15 steps in character development are a theoretical ideal, corresponding to the modal pathway that leads to full character development with high scores on all three character dimensions, which has been found to be optimal for healthy longevity, satisfaction, and meaning in life. This 15-step developmental sequence is consistent with prior qualitative descriptions of developmental stages by Piaget, Freud, and Erikson (Table 26–14) but allows for the actual nonlinearity in development that depends uniquely on each individual's identity. It also corresponds to recent findings on the stage-like development of intersubjectivity through reciprocal interactions among subjects. For example, imitation and mirroring of infants with their caretakers give rise to a basic sense of social connectedness and mutual acknowledgment with others. The first stage of intersubjectivity, after 2 months of age, involves the initial signs of intersubjective reciprocity and trust rather than automatic imitation. Next, there is the emergence of the sense of freedom in choices, such as joint attention to material objects. With the maturation of autobiographical memory around 4 years of age, there is an emergence of values that are jointly represented and negotiated with others.

By age 7 years, there is an initial capacity for allocentric perspective-taking that provides a basis for developing more self-transcendent values such as kindness and fairness. The conditions for cultivating intersubjective awareness correspond closely to the common factors for health promotion identified in person-centered therapeutics, as discussed in the introduction. More work is needed to synthesize the early work on personality development with recent work in neurobiology and the psychosocial sciences that recognizes the importance of interactions among multiple complex systems of learning and memory in humans.

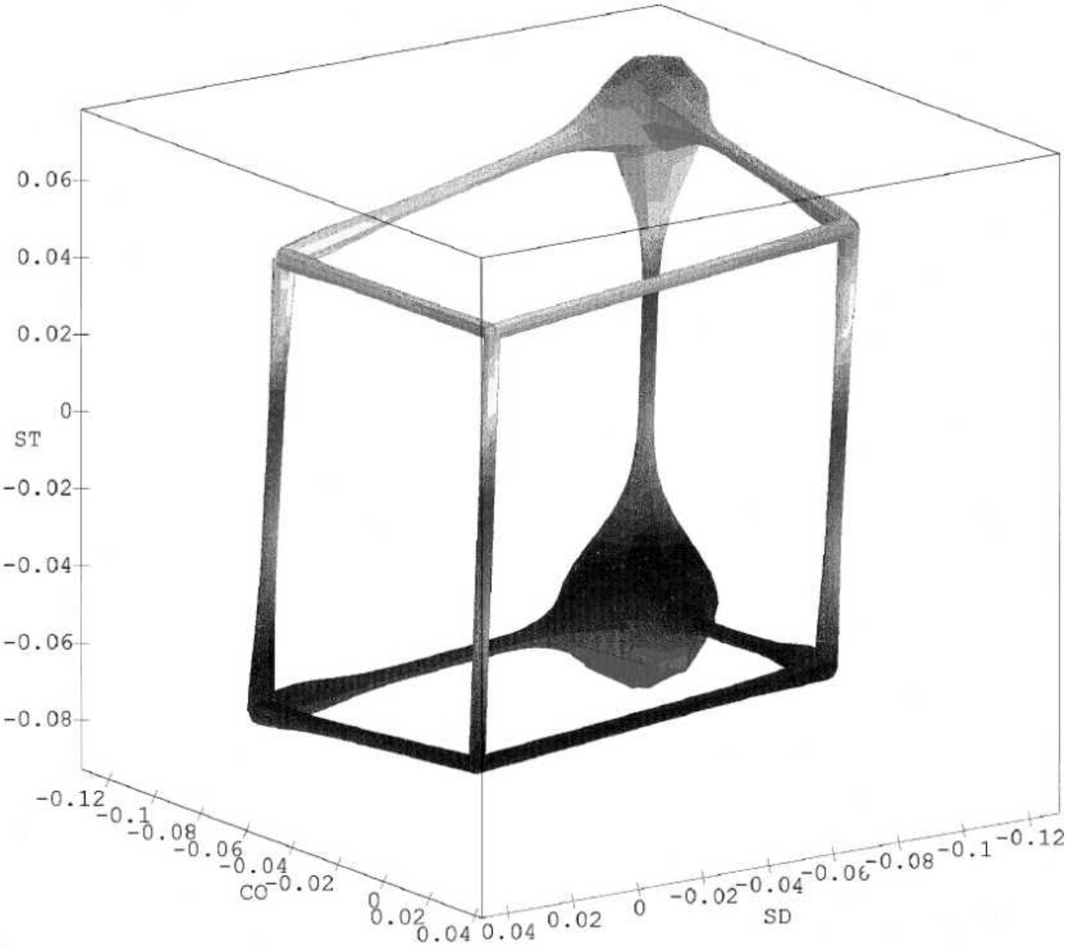

FIGURE 26–9. Most probable character outcomes for the explosive (borderline) antecedent temperament traits. CO, cooperativeness; SD, self-directedness; ST, self-transcendence.

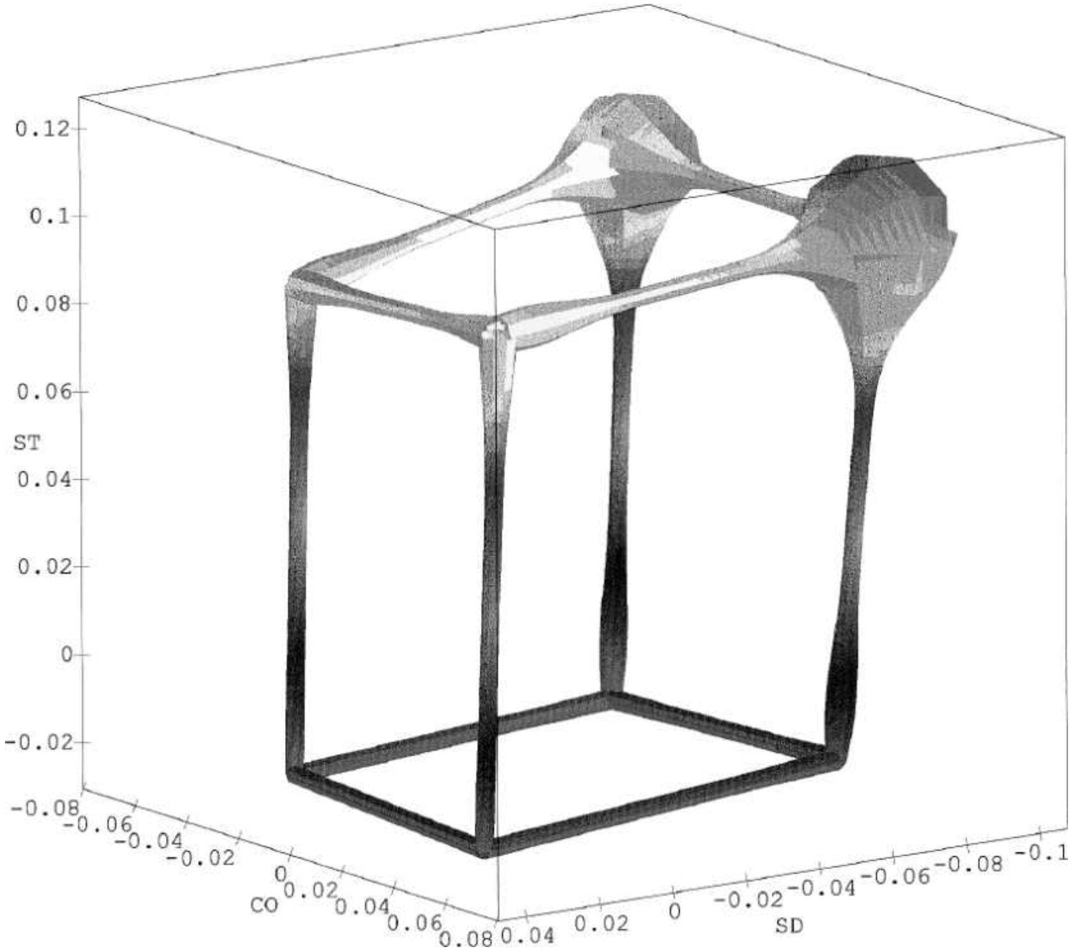

FIGURE 26–10. Most probable character outcomes for the sensitive antecedent temperament traits. CO, cooperativeness; SD, self-directedness; ST, self-transcendence.

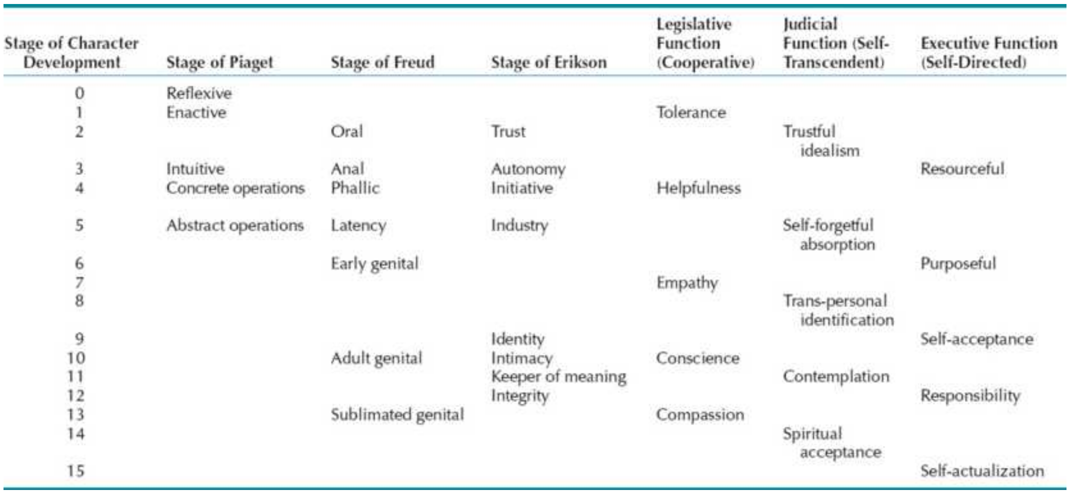
Table 26–14. Comparison of Different Descriptions of Character Development and Its Spiral Path



Stage of Character Development	Stage of Piaget	Stage of Freud	Stage of Erikson	Legislative Function (Cooperative)	Judicial Function (Self-Transcendent)	Executive Function (Self-Directed)
0	Reflexive					
1	Enactive			Tolerance		
2		Oral	Trust		Trustful idealism	
3	Intuitive	Anal	Autonomy			Resourceful
4	Concrete operations	Phallic	Initiative	Helpfulness		
5	Abstract operations	Latency	Industry		Self-forgetful absorption	
6		Early genital				Purposeful
7				Empathy		
8					Trans-personal identification	
9			Identity			Self-acceptance
10		Adult genital	Intimacy	Conscience		
11			Keeper of meaning		Contemplation	
12			Integrity			Responsibility
13		Sublimated genital		Compassion		
14					Spiritual acceptance	
15						Self-actualization

A person's identity can extend beyond the present to influence the trajectory of the development along a life project that can be creative if they develop strengths in all three dimensions of character or self-defeating if they do not. Observe that successive steps in character developmental form a spiral pattern, where each revolution around the spiral (presented as each of the five TCI tiers in Table 26–14) introduces a new set of developmental issues associated with the new set of component facets of the three major character traits. Furthermore, each revolution of the spiral depends on different levels in a hierarchy of intuitive awareness, as described earlier. For example, in early character development, during the first revolution around the spiral, a person encounters problems of trust versus mistrust, self-respect versus shame, and moderation versus indulgence; these are associated with Tolerance or Social Acceptance (facet 1 for Cooperativeness), Resourcefulness (facet 1 for Self-Directedness), and Idealism (facet 1 for Self-Transcendence). This depends substantially on a person's intuitive sense of being, whereas later developmental tasks depend on the intuitive senses of freedom and still later beauty, truth, and goodness. As can be inferred from Table 26–14, as they move along the spiral, people successively face new developmental tasks associated with new component facets in Self-Directedness, Cooperativeness, and Self-Transcendence. This spiral pattern of character development provides an opportunity to correct "developmental errors" that were made at any of the previous steps within the same trait. For example, as character develops around the spiral to reach a new step of Self-Directedness (e.g., responsibility), one gets "in line" historically with issues of self-acceptance, purposefulness, and resourcefulness (also steps of Self-Directedness but encountered during earlier revolutions) (Table 26–14). This alignment facilitates retrospective revisions of maladaptive responses to challenges that occurred at these earlier developmental levels. The possibility of "retrospective healing" of old character problems is important in planning the psychotherapy of patients with PDs. Namely, when addressing problems related to a certain developmental step, these patients are more susceptible to changes related to previous steps within the same character traits. In other words, learning about character in any one of the five planes of being can facilitate growth in self-awareness of similar processes in the other planes of being. This process of increasing maturation and integration of character continues throughout life because of the intrinsic human drive for coherence that is expressed as hope, love, and joy. Fortunately, vivid recollections in self-awareness allow healing by accepting the reality of what was given in experience and simultaneously allowing better understanding and imagination of creative solutions in the present and future.

Computer simulations of the self-organized development of character have been carried out, beginning with average initial temperament traits and taking into account all of the above contributing factors. These simulations found that children first increase in Self-Transcendence (i.e., become imaginative and enjoy fantasy), then increase in cooperativeness (i.e., become conforming and rule-based), and only later increase in self-directedness (i.e., behavior becomes increasingly self-reliant and autonomous). This prediction is consistent with the description of the stages of Ego development by Loevinger and her colleagues. This early sequence does not exclude the subsequent further development of other character dimensions in response to demands of changing social roles with age and/or changes in self-awareness. It is this subsequent development in response to external social pressures and ultimate existential questions that may explain adult self-actualization and moral development as described by Erikson, Kohlberg, and others. Consequently, intellectual components of the character traits are conscience (ethical principles such as fairness), contemplation, and responsibility (Table 26–14). Likewise, the ultimate spiritual components of the character traits are compassion, spiritual acceptance, and self-actualization (also called enlightened second nature).

PERSONALITY DISORDER

Normal versus Deviant Personality

Normal personality is usually defined (i) directly, using criteria of health ideals, or (ii) indirectly, as the opposite to deviant personality, or most frequently (iii) statistically, by behaviors that are most common in the given environment. However, the distinction between "normal" and "abnormal" personality is inherently relative as it relies on arbitrary cutoff points on the continuum between two extremes (very low and very high) of any behavior. This distinction is also context-dependent as the same behavior, manifested in different situations, could be viewed as normal or maladaptive (e.g., invariant cautiousness when danger is unlikely and the same trait when danger is likely). However, relying solely on the social or situational context to establish the diagnosis is problematic because PD involves many noninterpersonal traits as well (e.g., narcissistic persons satisfy many aspects of their grandiosity in fantasy). Here, personal deviance alone also does not reliably distinguish between normal behavior and PD (e.g., some individuals are very socially withdrawn without impairment in professional functioning or signs of personal suffering and distress). In other words, both personal and social aspects are needed to fully account for the symptoms of PD.

Classification of Personality Disorders

The leading classifications of PDs are the ICD of the World Health Organization and the DSM of the American Psychiatric Association. The ICD classification of PDs, 9th edition, relied extensively on Kurt Schneider's book "Psychopathic Personalities" and his description of 10 discrete socially deviant personality types. The 10th revision of ICD (ICD-10), published in 1987, corresponds more closely to the DSM system, however. Anglo-American concepts of PD originate in Pritchard’s description of moral insanity, which was later termed “sociopathy,” and finally became antisocial PD in DSM-II in 1968. However, other classified PDs in the DSM system can be traced to the work of Kurt Schneider. This chapter describes the DSM-5 classification of PD, which is the same as DSM-IV, originally published in 1994. It is, however, descriptively similar to ICD-10 and, for practical purposes, much of the following section on DSM-5 holds for ICD-10 as well.

It is also useful to be aware of changes introduced in the 11th edition of the ICD (ICD-11), which was approved by the WHO in 2019, and those proposed as alternative DSM-5 criteria that were rejected by the APA because of their unwieldy content and lack of scientific consensus. Both of these interesting criteria sets involve two major steps, as proposed by Cloninger in 2000: first, rating the presence of PD and its severity in terms of levels of adaptive functioning, and second, describing the specific traits that are prominent in the person.

In the ICD-11, personality is first rated as mild, moderate, or severe PD based on disturbed functioning of aspects of self or relations with others. Likewise, in the unofficial alternative DSM-5 criteria for PD, the presence of PD is based on mild, moderate, or severe personality dysfunction similar to Self-directedness (viz., identity and self-direction) and Cooperativeness (viz, empathy and intimacy), which are empirically are strong general predictors of official DSM PDs.

The ICD-11 and DSM-5 classifications then differ from one another in the second step. The separate classification of 10 PDs from ICD-10 is omitted in ICD-11 (except that borderline may be coded as a qualifier) but are retained in the official criteria of DSM-5, which are unchanged from DSM-IV. However, both official ICD-11 and unofficial research criteria for PD listed as an appendix to DSM-5 permit clinicians to code for five trait dimensions of personality dysfunction. However, empirical research shows that these two sets of trait domains actually describe four analogous trait domains: Negative Affectivity, Detachment, Dissociality/Antagonism, and Disinhibition. The fifth dimension proposed by these models is different: DSM-5 suggests Psychoticism (vs. Lucidity), whereas ICD-11 Anankastia (i.e., obsessional orderliness and perfectionism). The four descriptive qualifiers of PD correspond well to the four dimensions of temperament that distinguish subtypes of PD and have distinctive molecular biology as described by Cloninger and colleagues. These traits have been previously described by “the four As” by Mulder and Joyce: asthenic/anxious (i.e., negative affective features such as high Harm Avoidance, as in the DSM anxious cluster C and Galen’s melancholic temperament), adventurous/antisocial (i.e., dissocial and antagonistic features such as high Novelty Seeking, as in the DSM impulsive cluster B and Galen’s choleric temperament), asocial (i.e., detached features such as low Reward Dependence as in the DSM aloof cluster A and unlike Galen's sanguine temperament), and anankastic (i.e., perseverative and perfectionistic features such as high Persistence as in obsessional personalities and Galen's phlegmatic temperament). Empirical studies also show that four dimensions are adequate because Disinhibition and Anankastia may be bipolar extremes of a single dimension in self-reports and clinician ratings. In any case, it is difficult to choose between alternative descriptive models because factor analysis is a statistically indeterminate method and falsely assumes that personality is made up of independent traits rather than dynamically interactive systems of learning. For a reasonable scientific choice among alternative models, it is essential to take into account data about the genetics, neurobiology, and development of personality, as is done in the psychobiological model of personality but not the descriptive models of ICD-11 and DSM-5.

The individual personality traits used to subtype or qualify PD can also occur in combination with one another, so the produced categories are really not mutually exclusive, just as is also true of the corresponding DSM-IV clusters. More fine-grained descriptions can be used as in DSM, but the international classification needs to be efficiently applied around the world in places with limited resources, so ICD-11 requires only ratings of the severity of PD. Even more lengthy criteria like the DSM-5 may be too unwieldy and burdensome. The alternative DSM-5 criteria also involve categorical ratings that are not systematically derived from psychobiologically validated dimensions of personality, so the American Psychiatric Association judged it premature to endorse them. The official DSM-5 criteria, which are the same as in DSM-IV, will be described in detail here because of a wealth of clinical experience and research that is available about them.

DSM-5-TR Classification

According to DSM-5 and DSM-5-TR, the critical criterion for distinguishing deviant personality traits is the presence (evidence) of long-term maladaptation and inflexibility that are manifested as either subjective distress or socio-occupational functional impairment. According to the DSM-5, disorders of personality involve enduring patterns of inner experience and behavior that are manifest by at least two areas of cultural deviance involving perceptions and thoughts, emotional reactivity, interpersonal functioning, and impulse control.

The pattern is stable and of long duration, and its onset can be traced back at least to adolescence or early adulthood. It is inflexible and pervasive across a broad range of personal and social situations and leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.

It is unfortunate that these general criteria are rather vague because the most important assessment about personality is the level of maturity of character functions. The most commonly diagnosed PD is “not otherwise specified.” As a result, Cloninger has proposed that clinicians first evaluate the dimensions of character to determine whether there is any PD or not. As a second step, the features that distinguish subtypes can be described, but this is of secondary importance because the main focus of treatment is character development in every case.

PD subtypes classified in DSM-5 are Schizotypal, Schizoid, Paranoid (Cluster A), Narcissistic, Borderline, Antisocial, Histrionic (Cluster B), and Obsessive-Compulsive, Dependent, and Avoidant (Cluster C). In addition to these 10 “standard” disorders, the DSM-5 recognizes “personality change due to another medical condition,” “other specified PD” such as people with mixed features of more than one personality category, and “unspecified PD” for presentations in which the clinician chooses not to be specific or has insufficient information to be specific. Two other disorders, Passive-aggressive and Depressive that were recognized for further study in DSM-IV are omitted in DSM-5 but can be diagnosed as: “other specified PD.” The behaviors associated with borderline, passive-aggressive and depressive adaptations are regarded by many experts as nonspecific expressions of severe character dysfunction.

The DSM-5 arranges categorical PDs into three clusters, each sharing some clinical features (see Table 26–15): Cluster A includes three disorders with odd, aloof features, such as Paranoid, Schizoid, and Schizotypal. Cluster B includes four disorders with dramatic, impulsive, and erratic features, such as Borderline, Antisocial, Narcissistic, and Histrionic. Cluster C includes three disorders sharing anxious and fearful features, such as Avoidant, Dependent, and Obsessive-Compulsive. The ICD-11 may further separate the obsessive-compulsive cases from the avoidant and dependent cases. Several studies have supported the construct validity of these clusters except that the symptoms for compulsive disorder tend to form a separate fourth cluster, as proposed for ICD-11 and indicated in Table 26–15. Note that the three dimensions underlying Clusters A, B, and C (i.e., detachment, impulsivity, and fearfulness) correspond closely to normal temperament traits (i.e., low Reward dependence, high Novelty Seeking, and high Harm Avoidance, respectively), suggesting that variation in these temperament traits might be significant in distinguishing among the three clusters of disorders.

Table 26–15.
Qualitative Clusters and Subtypes of Personality Disorders According to the American Psychiatric Association (DSM-IV, 1994)

Cluster	Subtype	Discriminating Features
Odd/eccentric		
	Schizoid	Socially indifferent
	Paranoid	Suspicious
	Schizotypal	Eccentric
Erratic/impulsive		
	Antisocial	Disagreeable
	Borderline	Unstable
	Histrionic	Attention seeking
	Narcissistic	Self-centered
Anxious/fearful		
	Avoidant	Inhibited
	Dependent	Submissive
	Obsessive	Perfectionistic
Other specified		
	Passive–aggressive	Negativistic
	Depressive	Pessimistic

INDIVIDUAL PERSONALITY DISORDERS

General Diagnostic Guidelines

DSM-5 introduces the following general guidelines for the diagnosis of PD:

Many of the features of various PDs may also be seen during an episode of another mental disorder. The diagnosis of PD is only made when the features are typical of long-term functioning and are not limited to a discrete episode of another mental disorder. Likewise, when maladaptive behavior features are due to the direct psychological effects of another mental disorder, including substance use (e.g., various psychoactive substances including medication), diagnosis of PD is not warranted. However, it is possible to diagnose personality change due to another medical condition such as temporal lobe epilepsy; in this case, the medical condition must be specified along with the associated diagnosis of personality change.

Judgments about personality functioning must take into account one's ethnic, social, and cultural background. PD should not be confused with acculturation following immigration or with the expression of customs and religious and political values characteristic of one's culture of origin.

Diagnosis of specific PD may be made in children or adolescents when observed maladaptive personality traits are pervasive, persistent, and unlikely to be limited to a particular developmental stage or other major psychiatric illness. The features must be present for more than 1 year to diagnose a PD in an individual younger than 18 years. The only exception to this is Antisocial PD, which cannot be diagnosed in individuals younger than 18 years.

Clinical experience points to a potential sex bias in diagnosing PDs. Certain PDs are diagnosed more frequently in men (e.g., Antisocial and Schizoid), whereas some disorders are more frequently diagnosed in women (e.g., Borderline, Histrionic, and Dependent). Although it is likely that there exist real gender differences in the prevalence of these disorders, clinicians are cautioned not to diagnose certain PDs in males and females because of social stereotypes about typical gender roles and behaviors.

Observed maladaptive behavior traits must be pervasive, that is, manifest in a wide range of personal and social contexts (i.e., at home, at work, with family and friends), not isolated aspects of the person's life. The collection of data from collateral informants is thus considered critical to ensuring the high-quality personality assessment, diagnostic reliability, and validity.

In addition to "official" diagnostic criteria, DSM-5 specifies a group of "associated features." These features are not given in the form of explicit criteria (as their "official" counterparts) but rather as loose descriptions of optional but fairly frequent behaviors intended to help clinicians in cases in which the diagnosis is not certain.

Cluster A Personality Disorders

Paranoid Personality Disorder

CLINICAL CRITERIA. The hallmarks of Paranoid PD are excessive suspiciousness, and distrust of others expressed as a pervasive tendency to interpret actions of others as deliberately demeaning, malevolent, threatening, exploiting, or deceiving. Diagnostic features also include at least four of the following:

- Hypersensitivity to and unforgiveness of insults, slights, and rebuffs
- Unwarranted tendency to question the loyalty of friends or fidelity of spouse or sexual partners

- Reluctance to confide in others because of unwarranted fear that the information will be used against them
- Reads hidden demeaning or threatening meanings into benign remarks or events
- Preoccupation with “conspirational” explanations of and hidden demeaning or threatening meanings into benign events or remarks
- Persistently bears grudges (i.e., is unforgiving)
- Unwarranted tendency to perceive attacks on their character or reputation with angry reactions or counterattacks

Some of the associated features include the following:

- Excessive need to be self-sufficient and strong sense of autonomy
- Pervasive inability to relax and compromise
- Frequent involvement in legal disputes
- Frequently impress others as “fanatics”
- Tendency to form closed groups or “cults” consisting of people with similar beliefs
- Peculiar ability to generate fear in others

COMPLICATIONS. Brief reactive psychosis, particularly in response to stress.

COMORBIDITY. These patients are at increased risk for Major Depression, Obsessive-Compulsive Disorder, Agoraphobia, and Substance Abuse or Dependence. The most common co-occurring PDs are Schizotypal, Schizoid, Narcissistic, Avoidant, and Borderline.

Paranoid PD has been postulated to be a premorbid antecedent of Delusional Disorder, paranoid type.

IMPAIRMENT. Frequently only mild and typically includes occupational and social difficulties.

SEX RATIO. According to DSM-5, this disorder is more commonly diagnosed in males.

EPIDEMIOLOGY. Prevalence rates of 0.5% to 4.4% in the general population, 10% to 30% for psychiatric inpatients, and 2% to 10% for psychiatric outpatients are reported in DSM-IV-TR and DSM-5.

FAMILIAL PATTERN AND GENETICS. Some studies have demonstrated an increased prevalence of this PD among relatives of probands with chronic Schizophrenia and Delusional Disorder, paranoid type.

DIFFERENTIAL DIAGNOSIS. Paranoid PD is distinguished from Schizophrenia (especially paranoid type), Delusional Disorder, paranoid type, and a mood disorder with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. When a brief reactive psychosis with delusions complicates the clinical picture of Paranoid PD, this distinction is far more difficult. The duration of the latter and its frequent association with stress is usually sufficient for differential diagnosis.

Paranoid PD is sometimes difficult to distinguish from the following PDs:

- Schizotypal (which includes magical thinking, unusual perceptual experiences, oddities in speech, appearance, and thought processes)
- Obsessive-Compulsive, Schizoid, Borderline, and Histrionic (all with no prominent paranoid ideation)
- Avoidant (which includes fear of embarrassment)
- Antisocial (which includes personal gains in antisocial behavior)
- Narcissistic (which includes fear of having their “hidden” imperfections and flaws revealed)

Schizoid Personality Disorder

CLINICAL CRITERIA. The hallmarks of schizoid PD are a pervasive pattern of social detachment and a restricted range of expressed emotions in interpersonal settings beginning by early adulthood and present in a variety of contexts, as indicated by four or more of the following:

- Indifference to praise and criticism
- Preference for solitary activities and fantasy (“loners”)
- Lack of interest in sexual interactions
- Lack of desire or pleasure in close relationships
- Emotional coldness, detachment, or flattened affectivity
- No close friends or confidants other than family members
- Pleasure experienced in few if any activities

Some of the associated features include the following:

- Difficulty in expressing anger, even in response to direct provocation, which contributes to the impression of flattened affect
- Passivity in adverse circumstances
- Severe lack of social skills

COMPLICATIONS. Very brief reactive psychosis, particularly in response to stress.

COMORBIDITY. This PD sometimes appears as the premorbid antecedent of Delusional Disorder, Schizophrenia, or rarely Major Depression. The most common co-occurring PDs are Paranoid, Schizotypal, and Avoidant.

IMPAIRMENT. Frequently severe problems in social relations; occupational problems develop when interpersonal involvement is required, solitary work sometimes favorably affects overall performance.

SEX RATIO. According to DSM-5, this disorder is more commonly diagnosed in males and may cause more impairment in them.

EPIDEMIOLOGY. Prevalence rates varying from 3.1% to 4.9% have been reported (DSM-5).

FAMILIAL PATTERN AND GENETICS. An increased prevalence among the relatives of probands with Schizophrenia or Schizotypal PD has been reported.

DIFFERENTIAL DIAGNOSIS. Schizoid PD is distinguished from Schizophrenia, Delusional Disorder, and mood disorders with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. When a brief reactive psychosis complicates the clinical picture of Schizoid PD, this distinction is far more difficult. The duration of the latter and its frequent association with stress is usually sufficient for differential diagnosis.

Schizoid PD is distinguished from Autistic Disorder and Asperger’s Disorder by more severely impaired social interactions and stereotypic behaviors and interests in the latter two disorders. Schizoid disorder is distinguished from the following PDs:

- Schizotypal (which includes magical thinking, unusual perceptual experiences, oddities in speech, appearance, and thought processes)
- Avoidant (adequate emotionality in the latter, also social isolation due to the fear of embarrassment, not to indifference)
- Obsessive-Compulsive (adequate capacity for intimacy, despite sometimes excessive isolation due to perfectionism and workaholic attitudes)
- Paranoid (which includes suspiciousness, ideas of reference, and guarded facade)

Schizotypal Personality Disorder

CLINICAL CRITERIA. Schizotypal PD is characterized by social and interpersonal deficits as indicated by pervasive discomfort with reduced capacity for close relationships as well as cognitive and perceptual distortions and eccentric behavior (not severe enough to meet criteria for Schizophrenia). Diagnostic features also include at least five of the following:

- Ideas of reference (not delusions)
- Odd beliefs and magical thinking (superstitiousness, beliefs in clairvoyance, telepathy, “sixth sense”; in children and adolescents, bizarre fantasies or preoccupation)
- Unusual perceptual disturbances (illusions including bodily illusions, sensing a presence of a person nearby)
- Paranoid ideation and suspiciousness
- Odd, eccentric, peculiar behavior
- Lack of close friends, except family members
- Odd thinking and speech without coherence (e.g., vague, metaphorical, overelaborated, stereotypic)
- Inappropriate or constricted affect
- Social anxiety that does not diminish with familiarity and is associated with paranoid fears

PREDISPOSING FACTORS. Empirical findings about this disorder are difficult to interpret as there appear to be several clinical subtypes of this disorder, with potentially differential relationships to the schizophrenic spectrum. Adoption, family, and twin studies demonstrate an increased prevalence of schizotypal features in the families of schizophrenic patients, especially when schizotypal features were not associated with comorbid affective symptoms. Small anticipatory saccades that disrupt Smooth Pursuit Eye Movement, hypothesized to be a marker of genetic vulnerability to schizophrenia, have also been detected in schizotypal and introverted personalities. The nature of the relationship of this PD and Schizophrenia is still controversial, with some genetic studies not finding the relationship and some studies finding a pattern of gradation in multifactorial liability from schizotypal personality (mild) to broad schizophrenia (moderate) to narrow schizophrenia (severe).

COMPLICATIONS. Transient psychotic episodes, particularly in response to stress. Symptoms sometimes become so significant that they meet the criteria for Schizophreniform Disorder, Delusional Disorder, and Brief Psychotic Disorder.

COMORBIDITY. More than half of these patients have had at least one episode of Major Depression, and 30% to 50% have Major Depression concurrent with this PD. The most common co-occurring PDs are Schizoid, Paranoid, Avoidant, and Borderline.

IMPAIRMENT. Typically includes occupational and social difficulties.

SEX RATIO. Unknown; frequently diagnosed in females with fragile X syndrome.

EPIDEMIOLOGY. Prevalence rates of 3.9% to 4.6% in the general population are reported in DSM-5. Earlier reports suggested a range between 1% and 6%. It may be less common in clinical populations than in the general population, according to DSM-5.

FAMILIAL PATTERN AND GENETICS. An increased prevalence of this PD among the first-degree relatives of probands with Schizophrenia. Also, an increased prevalence of Schizophrenia and other psychoses in the relatives of probands with Schizotypal PD. The disorder itself tends to aggregate in families (DSM-5).

DIFFERENTIAL DIAGNOSIS. Schizotypal PD is distinguished from Schizophrenia, Delusional Disorder, and mood disorders with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. When a brief reactive psychosis with delusions complicates the clinical picture of Schizotypal Personality, this distinction is far more difficult.

Schizotypal PD is difficult to distinguish from the heterogeneous group of solitary, odd children whose behavior is characterized by social isolation, eccentricity, and peculiarities in language seen in Autistic Disorder, Asperger's Disorder, and Expressive and Mixed Receptive–Expressive Language Disorder. Communication disorders might be distinguished by the primacy and the severity of the disorder in language accompanied by compensatory efforts of the child to communicate by other means and also by specialized language assessment. Autistic Disorder and Asperger's Disorder are distinguished on the basis of more severely impaired social interactions and stereotype behaviors and interests in the latter two disorders. Schizotypal disorder is distinguished from the following PDs:

- Schizoid and Paranoid (which rarely have magical thinking, unusual perceptual experiences, or oddities in speech, appearance, and thought processes)
- Narcissistic (with predominant sense of grandiosity, fragile self-esteem, and fear of having their "hidden" imperfections or flaws revealed)
- Avoidant (which rarely has oddities in appearance and behavior, and here fear of embarrassment, not disinterest and detachment, causes social avoidance and isolation)
- Borderline (characterized by affective instability and stormy relationships as well as impulsive and manipulative behavior)

Cluster B Personality Disorders

Antisocial Personality Disorder

CLINICAL CRITERIA. The hallmarks of antisocial PD are a pervasive disregard for and violation of rights of others occurring since the age of 15 years and continuing into adulthood. A person has to be 18 years of age or older, and there has to be evidence of conduct disorder before the age of 15 years (conduct disorder involves a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate social rules are violated; the examples include aggression to people and/or animals, destruction of property, deceitfulness or theft, serious violation of rules). Diagnostic features also include at least three of the following:

- Failure to conform to social norms (resulting in frequent arrests)
- Deceitfulness, including lying and conning others for personal profit or pleasure
- Impulsivity or failure to plan ahead
- Irritability and aggressiveness, including repeated physical fights or assaults
- Recklessness, with disregard for the safety of self and others
- Irresponsibility, indicated by the failure to honor financial obligations or to sustain consistent work behavior
- Lack of remorse, indicated by indifference or rationalizing having hurt, mistreated, or stolen from others

Some of the associated features include the following:

- Promiscuity and inability to sustain a monogamous relationship
- Lack of empathy, cynicism, contempt for feelings, rights, or suffering of others
- Inflated and arrogant self-appraisal
- Abusiveness and irresponsibility toward children

COMPLICATIONS. Dysphoria, tension, low tolerance for boredom, depressed mood, and premature, violent death.

COMORBIDITY. These patients are at increased risk for Impulse Control Disorders, Major Depression, Substance Abuse or Dependence, Pathologic Gambling, Anxiety Disorders, and Somatization Disorder. The most common co-occurring PDs are Narcissistic, Borderline, and Histrionic.

IMPAIRMENT. Extremely variable typically includes social difficulties.

SEX RATIO. According to DSM-5, this disorder is more commonly (3:1) diagnosed in males.

EPIDEMIOLOGY. Prevalence rates of 3% for males and 1% for females in the general population, 3% to 30% in clinical settings with even higher rates for forensic samples and substance abusers, have been reported. As noted in DSM-5, there has been some concern that this disorder may be underdiagnosed in females, given the emphasis on aggressive items in diagnosing Conduct Disorder.

High frequency of Antisocial PD is associated with low socioeconomic status and urban settings.

COURSE. After the age of 30 years, both the most flagrant antisocial behaviors (promiscuity, crime) and the less severe behaviors and substance use tend to decrease. Even after the severe antisocial behavior “burns out,” people diagnosed with antisocial PD usually continue to be irritable, impulsive, and detached.

FAMILIAL PATTERN AND GENETICS. Antisocial PD is more frequent among the first-degree biologic relatives of probands with this disorder than in other relations. Biologic relatives of females with Antisocial PD are at increased risk for the same disorder than biologic relatives of males with Antisocial PD. Genetic studies have suggested familial transmission of Antisocial PD, Substance Use, and Somatization Disorder, the former two being characteristic of males, the latter of females in the same family.

Adoption studies have shown that both genetic and environmental factors contribute to the risk for this disorder.

Both adopted, and biologic children of parents with Antisocial PD are at increased risk for this disorder. Conduct Disorder (before the age of 10 years) and accompanying Attention-Deficit Hyperactivity Disorder increase the likelihood of developing antisocial personality in adult life. Conduct Disorder is more likely to develop into Antisocial Disorder with erratic parenting, neglect, or inconsistent parental discipline.

DIFFERENTIAL DIAGNOSIS. Antisocial PD is distinguished from Bipolar Disorder, manic on the basis of episodic course, and euphoric mood of the latter. Antisocial PD is distinguished from the following PDs:

- Narcissistic (which rarely manifests serious criminality, aggression, and deceit and is characterized by an excessive need for admiration and envy of others)
- Histrionic (which includes seductiveness, attention-seeking, superficiality, and rarely serious criminality and aggressiveness)
- Borderline (which includes manipulativeness to gain nurturance and affective instability). Contrary to the common belief that borderline personalities rarely commit crimes, individuals with explosive or borderline temperaments (high Harm Avoidance, high Novelty Seeking, and low Reward Dependence) frequently manifest antisocial behaviors (“secondary” psychopathy). Secondary psychopathy is distinguished from antisocial personality proper (or

"primary" psychopathy) as the latter has a different temperament profile: high Novelty Seeking with low Harm Avoidance and low Reward Dependence, corresponding to the adventurous temperament profile.
- Paranoid (which includes suspiciousness, guarded attitude, rarely serious antisocial behaviors)
- Adult Antisocial Behavior (with no personality pathology in the background)

Narcissistic Personality Disorder

CLINICAL CRITERIA. The hallmarks of Narcissistic PD are a pervasive sense of grandiosity (in fantasy or in behavior), need for admiration, lack of empathy, and chronic intense envy. Diagnostic features also include at least five of the following:

- Grandiose sense of self-importance and specialness
- Preoccupation with fantasies of unlimited success, power, brilliance, beauty, or ideal love
- Sense of entitlement
- Regards self as "special" and unique
- Interpersonal exploitativeness such as taking advantage of others to achieve own needs
- Lack of empathy
- Excessive need for admiration and acclaims
- Intensive and chronic envy
- Arrogant and haughty attitude

Some of the associated features include the following:

- Fragile self-esteem (which exclusively depends on external admiration) with hypersensitivity to criticism
- High achievements more frequent than in any other PD
- Strong feelings of shame and humiliation
- Exhibitionism (behavior motivated by the pleasure of being looked at)
- Fear of having their "hidden" imperfections and flaws revealed

COMPLICATIONS. Social withdrawal, depressed mood, and Dysthymic or Major Depressive Disorder in reaction to criticism or failure.

COMORBIDITY. These patients are at increased risk for Major Depression and Substance Abuse or Dependence (especially cocaine use). The most common co-occurring PDs are Borderline, Antisocial, Histrionic, and Paranoid.

IMPAIRMENT. Frequently severe, typically includes marital problems and interpersonal relationships in general.

SEX RATIO. According to DSM-5, this disorder is more commonly diagnosed in males (50% to 75% of diagnosed cases are males).

COURSE. Chronic. However, narcissistic symptoms tend to diminish after the age of 40 years, when pessimism usually develops.

EPIDEMIOLOGY. Prevalence rates of 2% to 16% in the clinical population, less than 1% in the general population are reported in DSM-IV-TR and DSM-5.

PREDISPOSING FEATURES. There may be a higher risk for this PD in the offspring of narcissistic parents who impart on their children an unrealistic sense of grandiosity. In addition, most narcissistic persons are realistically talented, beautiful, or highly intelligent, as these features serve as the nucleus around which the sense of specialness is further organized.

DIFFERENTIAL DIAGNOSIS. Narcissistic PD is distinguished from Manic or Hypomanic episodes by the episodic course, euphoria, and functional impairments in the latter two. Narcissistic personality is distinguished from the following PDs:

- Antisocial (narcissistic exploitativeness is more driven by the wish to establish one’s dominance than by material gains, history of Conduct Disorder, no excessive need for admiration)
- Borderline (which includes unstable self-concept, chaotic behaviors, self-destructive gestures, chronic anxiety, and rarely high achievements)
- Histrionic (which includes capacity for empathy, emotional display, and rarely unscrupulousness and exploitation of others)
- Obsessive-Compulsive (which includes inflexibility, detail orientedness, and social isolation in addition to perfectionism and belief that others cannot do things as well)
- Paranoid and Schizotypal (which include suspiciousness and social withdrawal).

Histrionic Personality Disorder

CLINICAL CRITERIA. The hallmarks of histrionic PD are pervasive and excessive self-dramatization, excessive emotionality, and attention-seeking. Diagnostic features also include at least five of the following:

- Inappropriate sexual seductiveness or provocativeness

- Excessive need to be in the center of attention
- Rapidly shifting and shallow expression of emotions
- Suggestibility
- Physical appearance used for attention-seeking purposes
- Impressionistic speech lacking detail
- Self-dramatization, theatricality, exaggerated expression of emotions
- Relationships are considered more intimate than they really are

Some of the associated features include the following:

- Difficulties in achieving emotional intimacy in romantic or sexual relationships
- Craving for excitement and stimulation
- Promiscuity or complete sexual naiveness
- Low tolerance for delayed gratification

COMPLICATIONS. Frequent suicidal gestures and threats to coerce better caregiving. Interpersonal relations are unstable, shallow, and generally ungratifying. Frequent marital problems secondary to the tendency to neglect long-term relationships for the excitement of new relationships.

COMORBIDITY. These patients are at increased risk for Major Depression, Somatization Disorder, and Conversion Disorder. The most common co-occurring disorders are Narcissistic, Borderline, Antisocial, and Dependent.

IMPAIRMENT. Frequently only mild and typically includes personal, romantic relationships.

SEX RATIO. There seems to be a general agreement that this disorder occurs far more frequently among women. According to DSM-5, the disorder might be equally frequent among men and women.

EPIDEMIOLOGY. Prevalence rates of about 2% in the general population, 10% to 15% for psychiatric inpatients and outpatients are reported in DSM-IV-TR and DSM-5.

FAMILIAL PATTERN AND GENETICS. This disorder tends to run in families. A genetic “link” between Histrionic and Antisocial PD and Alcoholism has been suggested.

DIFFERENTIAL DIAGNOSIS. Histrionic PD is distinguished from the following PDs:

- Antisocial (which includes antisocial behaviors and crime to gain profit, power, or some other material gratification, history of Conduct Disorder, no excessive self-dramatization, no exaggerated emotional expression)

- Borderline (which includes unstable self-concept, chaotic behaviors, self-destructive gestures, chronic anxiety, identity disturbance)
- Narcissistic (which includes fear of having their “hidden” imperfections and flaws revealed, sense of grandiosity and specialness)

ANTISOCIAL, NARCISSISTIC, AND HISTRIONIC SPECTRUM. Narcissistic, Antisocial, and Histrionic PDs qualify for the so-called spectrum disorders. The three disorders have been shown to aggregate in the same family and to co-occur in the same person. Phenotypically distinguishable disorders may be referred to as spectrum disorders if they meet the above two conditions. Spectrum disorders sometimes reflect a differential expression of the same liability. Antisocial, Narcissistic, and Histrionic PDs exemplify the spectrum in which proneness to impulsivity and aggression (associated with high Novelty Seeking) interferes with character development and maturity. Empirical data show that symptoms of the three disorders tend to group around impulsivity, aggression, and dramatic affects. A spectrum disorder may also reflect a less deviant form of the other on an underlying liability scale. In that regard, the underlying antisocial behaviors increase in severity as one proceeds from Histrionic Personality (manipulation) via Narcissistic Personality (exploitation) and Antisocial Personality (violent and property crime).

Borderline Personality Disorder

CLINICAL CRITERIA. The hallmarks of Borderline PD are pervasive and excessive instability of affects, self-image, and interpersonal relationships, as well as marked impulsivity. Diagnostic features also include at least five of the following:

- Frantic efforts to avoid real or imagined abandonment. **Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5
- Unstable and intense interpersonal relationships, with alternating between idealization and devaluation
- Markedly and persistently unstable self-image or sense of self
- Impulsivity in at least two potentially self-damaging areas (spending, sex, substance abuse, binge eating, reckless driving). **Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5
- Recurrent suicidal behavior, gestures, threats, or self-mutilating behaviors
- Instability of affect due to marked reactivity of mood
- Chronic feelings of emptiness
- Inappropriately intense anger or difficulty controlling anger
- Stress-related, transient paranoid ideation or dissociative symptoms

Some of the associated features include the following:

- Tendency to undermine self when close to realizing a goal
- Feeling more secure with nonhuman objects (pets, inanimate objects) than in interpersonal relationships

PREDISPOSING FACTORS. Numerous studies have pointed to early traumatic experiences in the etiology of this PD. Recently, a tripartite etiopathogenetic model, including childhood trauma, vulnerable temperament, and a series of triggering events, has been formulated. Both dynamic and biologic psychiatry agree that a combination of early traumatic events and certain biologic vulnerabilities (mostly in the emotional domain) represent primary etiologic factors for this disorder. Familial aggregation of Borderline PD has been repeatedly demonstrated.

COMPLICATIONS. Psychotic-like symptoms (hallucinations, body image distortions, hypnagogic phenomena, ideas of reference) in response to stress; premature death or physical handicaps from suicide and suicidal gestures, failed suicide, and self-injurious behavior.

COMORBIDITY. These patients are at increased risk for Major Depression, Substance Abuse or Dependence, Eating Disorder (notably Bulimia), Post-Traumatic Stress Disorder, and Attention-Deficit Hyperactivity Disorder. Borderline PD co-occurs with most other PDs.

IMPAIRMENT. Frequent and severe; frequent job losses interrupted education, broken marriages.

SEX RATIO. According to DSM-5, this disorder is more commonly diagnosed in females (75% of diagnosed cases are females).

COURSE. Variable. Most commonly follows a pattern of chronic instability in early adulthood, with episodes of serious affective and impulsive dyscontrol. The impairment and the risk of suicide are the greatest at the young adult years and gradually wane with advancing age. In the fourth and fifth decades, these individuals tend to attain greater stability in their relationships and functioning.

EPIDEMIOLOGY. Prevalence rates of about 2% in the general population, 10% for psychiatric outpatients, 20% for psychiatric inpatients, and 30% to 60% among patients with PDs are reported in DSM-5. The diagnosis is more common in younger than in older samples, suggesting a natural tendency toward maturation and remission.

FAMILIAL PATTERN AND GENETICS. Physical and sexual abuse, neglect, hostile conflict, and early parental loss or separation are common in the childhood histories of patients with this disorder. Borderline PD is five times more common among relatives of probands with this disorder than in the general population. It also increases the familial risk for Antisocial PD, Substance Abuse, and Mood Disorders.

DIFFERENTIAL DIAGNOSIS. Borderline PD is distinguished from Mood Disorder, Dysthymic Disorder, and Cyclothymia (with depression and mood swings mimicking borderline affective problems) based on efforts to avoid abandonment, unstable relationships with alternating between idealization and devaluation, identity disturbance, impulsivity in potentially self-damaging areas, chronic feelings of emptiness, and inappropriately intensive anger or difficulty controlling anger (these symptoms are rarely observed in Mood Disorder, Dysthymia, or Cyclothymia). Borderline disorder shares many features and is difficult to distinguish from all other PDs, frequently as an exclusion diagnosis based on typical clinical symptoms for other PDs. Borderline disorder is distinguished from Identity Problems (the latter is limited to a developmental stage).

Cluster C Personality Disorders

Avoidant Personality Disorder

CLINICAL CRITERIA. The hallmarks of avoidant PD are pervasive and excessive hypersensitivity to negative evaluation, social inhibition, and feelings of inadequacy. Diagnostic features also include at least four of the following:

- Avoidance of occupational activities that involve significant interpersonal contact because of fears of criticism, rejection, or disapproval
- Unwillingness to be involved with others unless certain of being liked
- Restraint in intimate relationships because of the fear of being shamed or ridiculed
- Preoccupation with being criticized or rejected in social situations
- Inhibition in new social situations because of feelings of inadequacy
- Reluctance to take personal risks or to engage in any new activities because they may prove embarrassing
- Views self as socially inept, personally unappealing, or inferior to others

Some of the associated features include the following:

- Fearful and tense demeanor
- Fear of blushing or crying in front of others in response to criticism

- Social isolation is accompanied by craving social relations and fantasizing about ideal relationships with others

COMPLICATIONS. Social phobia.

COMORBIDITY. These patients are at increased risk for Mood and Anxiety Disorders (especially Social Phobia, generalized type). The most common co-occurring disorders are Schizotypal, Schizoid, Paranoid, Dependent, and Borderline.

IMPAIRMENT. Can be severe and typically includes occupational and social difficulties.

SEX RATIO. According to DSM-5, this disorder is equally frequent in males and in females.

EPIDEMIOLOGY. Prevalence rates of 0.5% to 2% in the general population and 10% for psychiatric outpatients are reported in DSM-IV-TR and DSM-5.

COURSE. Frequently begins in childhood with shyness and fear of strangers and new situations. Disfiguring illness and shyness in childhood predispose children for this PD.

DIFFERENTIAL DIAGNOSIS. Avoidant PD is very difficult to distinguish from Social Phobia (many authors believe that these are alternative labels for the same or similar condition). In Social Phobia, specific situations rather than interpersonal contact are avoided. Panic Disorder with Agoraphobia also manifests avoidance but usually after the onset of panic attacks. Avoidant disorder is distinguished from the following PDs:

- Schizotypal and Schizoid (social isolation of avoidant personalities is accompanied by the desire for social relations, which is not observed in Schizoid and Schizotypal PD)
- Paranoid (which includes guarded attitude, preoccupation with hidden meanings, and conspirational explanations of being events)
- Dependent (which is focused on being taken care of rather than on the fear of negative evaluation)

Dependent Personality Disorder

CLINICAL CRITERIA. The hallmarks of Dependent PD are pervasive and excessive need to be taken care of that leads to clinging behavior, submissiveness, fear of separation, and interpersonal dependency.

Diagnostic features also include at least five of the following:

- Difficulty in making everyday decisions without excessive reassurance and advice from others
- Needs others to assume responsibility for major areas of their life
- Difficulties expressing disagreement with others because of fear of loss of support or approval. **Note:** Do not include realistic fears of retribution
- Lack of initiative
- Unrealistic preoccupation with fears of being left to take care of self
- Urgent search for another relationship as a source of care and support when a close relationship ends
- Extensive efforts to obtain nurturance and support from others (to the point of volunteering to do unpleasant things)
- Uncomfortable and helpless feelings when alone because of exaggerated fears of being unable to take care of self. Pessimism, self-doubt, self-devaluation.

Some of the associated features include the following:

- Prominent pessimism and self-doubt since childhood
- Hypersensitive to criticism and rejection
- Anxious avoidance of responsibility

COMPLICATIONS. Mood Disorders, Anxiety Disorders, Adjustment Disorder, Social Phobia. Low socioeconomic status, poor family, and marital functioning.

COMORBIDITY. These patients are at increased risk for Major Depression, Anxiety Disorders, and Adjustment Disorder. The most common co-occurring disorders are Histrionic, Avoidant, and Borderline.

IMPAIRMENT. Frequently only mild and typically includes interpersonal relationships and occupational functioning if independence is required.

SEX RATIO. Equally frequent in males and females (DSM-5).

EPIDEMIOLOGY. Prevalence rates of 0.5% to 0.6% are reported in DSM-5 for this specific diagnosis, even though dependency is a prominent feature of many PDs.

FAMILIAL PATTERN AND GENETICS. Unknown. Chronic physical illness or Separation Anxiety Disorder may predispose to Dependent PD.

DIFFERENTIAL DIAGNOSIS. Dependent disorder is distinguished from dependency seen in Mood Disorders, Panic Disorder, Agoraphobia, and as a result of a general medical condition. Dependent disorder is distinguished from the following PDs:

- Borderline (which includes unstable, stormy relationships and the reaction to abandonment with rage, emptiness, and demands as opposed to increasing appeasement and submissiveness seen with dependent personalities)
- Histrionic (which includes gregarious flamboyance with active demands for attention)
- Avoidant (which includes social isolation because of the fear of negative evaluation as opposed to clinging and submissive behavior of dependent personalities)

Obsessive-Compulsive Personality Disorder

CLINICAL CRITERIA. The hallmarks of Schizoid PD are pervasive and preoccupation with orderliness, perfectionism, and mental and interpersonal control at the expense of flexibility, openness, and efficiency. Diagnostic features also include at least four of the following:

- Preoccupation with details, rules, lists, order, procedures, organization, or schedules to the extent that the major point of the activity is lost
- Perfectionism that interferes with task completion
- Excessive devotion to work and productivity to the exclusion of leisure activities and friendships (not accounted for obvious economic necessity)
- Overconscientiousness, scrupulousness, and inflexibility about matters of morality, ethics, or values (not accounted for by religion or culture)
- Inability to discard worn off or worthless objects with no sentimental value
- Reluctance to delegate tasks or work with others unless they submit exactly to their way of doing things
- Stinginess (money viewed as something to be hoarded for future catastrophes)
- Rigidity and stubbornness

Some of the associated features include the following:

- Decision-making difficulties when no strict rules or established procedures dictate correct action
- Anger and frustration when not able to maintain control of the physical or interpersonal environment (anger typically not expressed directly)
- Excessive attentiveness to their relative status in dominance–submission relationships
- Controlled and restricted emotional expression, reserved personal style
- Formal and serious quality of everyday relationships

PREDISPOSING FACTORS. It has been repeatedly demonstrated that Obsessive-Compulsive PD and Obsessive–Compulsive Disorder frequently coexist. Obsessions and compulsions have been repeatedly linked to high central serotonergic function, which is associated with anxiety in general, supporting the hypothesis that obsessions and compulsions represent psychological and behavioral mechanisms reflecting underlying anxiety.

COMPLICATIONS. Distress and difficulties when confronted with new situations that require flexibility and compromise. Myocardial infarction (secondary to features typical of type A personalities, such as time urgency, hostility, competitiveness).

COMORBIDITY. These patients are at increased risk for Major Depression and Anxiety Disorder. Equivocal evidence for increased risk of Obsessive-Compulsive Disorder.

IMPAIRMENT. Frequently severe, it typically includes occupational and social difficulties.

SEX RATIO. According to DSM-5, this disorder is twice as common in males than in females.

EPIDEMIOLOGY. Prevalence rates of 2% to 8% in the general population and 3% to 10% for psychiatric outpatients are reported in DSM-IV-TR and DSM-5.

FAMILIAL PATTERN AND GENETICS. Some studies have demonstrated familial aggregation of this disorder.

DIFFERENTIAL DIAGNOSIS. Obsessive-compulsive PD is distinguished Obsessive–Compulsive Disorder based on true obsessions and compulsions in the latter. This PD is distinguished from the following PDs:

- Schizoid (which includes lack of capacity for intimacy and social isolation secondary to emotional detachment, as opposed to devotion to work, discomfort with emotions)
- Antisocial (which includes material goals in antisocial behavior and criminality as opposed to the hypermorality of obsessive personalities)
- Narcissistic (which includes a sense of grandiosity, self-aggrandizement, exhibitionism, and fear of having their “hidden” imperfections and flaws revealed)

Other Personality Disorders

Personality Change due to Another Medical Condition. This diagnosis is made when a persistent change in someone's personality is due to another medical condition, such as temporal lobe epilepsy. The disturbance must be marked and the direct result of the other medical condition, which must be specified. The disturbance cannot be better explained by another mental disorder and does not occur exclusively during the course of a delirium. It must meet the general criteria for a PD in terms of subjective distress or impairment in functioning. Several subtypes can be specified on the basis of the predominant feature:

- Labile type
- Disinhibited type
- Aggressive type
- Apathetic type
- Paranoid
- Other
- Combined (more than one of the above features)
- Unspecified (e.g., if the change is due to substance abuse and features are not specified)

Other Specified Personality Disorder

This disorder is diagnosed when the DSM-5 criteria for dysfunctional personality (i.e., general criteria for a PD) are met, but no specific criteria for any of the subtypes are observed. For example, a patient may not meet the criteria for any of the classified disorders but still manifest features from more than one PD ("mixed PD"), which, together, cause distress or impairments in social or professional functioning. This category is also used when the clinician judges that a specific PD that is not included in DSM-5 is appropriate (e.g., depressive personality or passive-aggressive personality).

Unspecified Personality Disorder

This diagnosis is applied when the general criteria for a PD are met, and the clinician has insufficient information to make a specific diagnosis or chooses not to communicate the specific reason that the presentation does not meet the criteria for a specific diagnosis.

Table 26–16.
Quantifiable (Dimensional) Features of Personality Disorder

- Consistent features
  - Low self-directedness
    - Irresponsible, blaming
    - No mature goals
    - Resourceless, helpless
    - Poor self-esteem
    - Undisciplined
  - Low cooperativeness
    - Intolerant of others
    - Lack of empathy
    - Unhelpful
    - Revengeful
    - Unprincipled
- Variable features
  - High persistence (obsessive-compulsive symptoms only)
  - Low reward dependence (odd cluster only)
  - High novelty-seeking (erratic cluster only
  - High harm avoidance (anxious cluster only)

Summary Description of the DSM-5-TR Personality Disorders

Qualitative features that are diagnostic of a PD as classified in DSM-5 are summarized in Table 26–16. Cloninger has also provided practical criteria to detail these general features so that a clinician may first decide whether a person has any PD before proceeding to diagnose a specific cluster or category of illness. The general features of all PDs are the character traits, whereas the clusters and categories are determined by additional temperament features.

Disadvantages of DSM-5-TR Classification

In addition to problems shared by all categorical models of personality (discussed later), the DSM classification has its specific limitations.

First, DSM-5 is an etiologically “atheoretical” classification of PD based solely on descriptive criteria derived from observations of prototypical cases. This “atheoretical” approach was expected to stimulate work on the etiopathogenetic understanding of deviant behaviors classified as PDs. Unfortunately, this has not been the case. The introduction of descriptive criteria in DSM-III has inspired extensive research of some basic psychometric aspects of the PD diagnosis but rarely studies of etiology, underlying dynamics, or pathogenesis. While this emphasis on psychometrics obviously reflects an attempt of this new field to delineate its subject, it is also reflective of the purely descriptive approach, which provided no etiopathogenetic models or hypotheses for testing. For example, the DSM criteria have been of little or no help in developing the psychobiological model described here. In contrast, the experimental animal and twin studies on which the psychobiological model of personality was built have now been confirmed and extended by extensive work in human beings using functional brain imaging and person-centered genomic–phenomic analyses.

Second, the DSM-IV describes as pathognomonic for PD maladaptive response patterns that are “enduring,” that is, appearing before adulthood with long-term duration. In practice, however, it can be difficult to distinguish long-term maladaptation indicative of PD from chronic personality changes caused by other factors, such as other mental disorders (e.g., chronic depression), long-term situational factors (e.g., job-related timidity), and by other medical disorders (e.g., irritability associated with hyperthyroidism).

Third, the DSM definition of PDs is inherently imprecise, as it requires that maladaptive behaviors cause **clinically significant** subjective distress or **clinically significant** impairment in social and occupational function, or both. **“Subjective distress”** usually presents as low self-esteem, anxiety, guilt, depression, and hypochondriasis. These symptoms are frequently diagnosed as another mental disorder while the background PD is overlooked, especially now that the multiaxial system of DSM-IV that distinguished personality variation from other disorders has been dropped in DSM-5 and DSM-5-TR. The quantifier “significant” is an arbitrary diagnostic element that can hardly be made objective, as shown by allowing a clinician’s judgment without qualification or justification to determine what is significant.

CLINICAL AND PSYCHOMETRIC ISSUES

Egosyntonic and Alloplastic Nature of Personality Disorder

Patients with PD typically blame other people or unfavorable circumstances for their own problems. This externalizing of responsibility is a result of the following two characteristics. First, most of these patients perceive their own deviant behaviors as appropriate and adequate; in other words, their symptoms are egosyntonic. The exceptions to this are patients with Dependent and Avoidant PD. Both disorders are characterized by prominent anxiety associated with maladaptive behaviors, and this frequently causes the patients to perceive their symptoms as disturbing, that is, egodystonic.

Second, patients with PD try to change others, not themselves; in other words, their attitude is alloplastic. The exceptions to this rule are patients with Avoidant and Schizoid PD. Avoidant persons usually try to improve their own performance to avoid negative evaluations by others. Schizoid personalities are socially detached to the extent that they are usually indifferent to what others might do, think, or feel.

Personality Disorder: Social or Clinical Diagnosis?

One of the general DSM-5 requirements for PD is that maladaptive behavior “deviates markedly from the expectations of the individual’s culture.” This requirement introduces a significant social connotation to what was meant to be a clinical classification. Indeed, clinicians frequently diagnose PD based solely on the extent to which certain behavior is acceptable within the local society.

Sociocultural pressures are always norm-favoring, promoting phenotypes that fall within the range of accepted behavioral norms. As shown later in the text, most temperament profiles with high Reward Dependence have a low incidence of diagnosed PD, whereas those with high Harm Avoidance and/or high Novelty Seeking increase this risk. In most Western societies, the normative phenotype is not the one with average personality traits (as one would expect given the adaptive flexibility of such configuration) but the one with high Reward Dependence (high Reward Dependence also means much easier conditioning of socially accepted behaviors than is the case with other temperament traits).

In a similar way, child psychiatry classifies three broad groups of mental disorders in children: one group is characterized by high Novelty Seeking (e.g., externalizing disorders such as Attention-Deficit Hyperactivity Disorder, Conduct Disorder), one group by high harm Avoidance (e.g., internalizing disorders such as Depressive and Anxiety Disorders), and one group by low Reward Dependence (asocial disorders such as Autism). Children with these extreme temperaments are diagnosed and treated to change their behavior, whereas children with high Reward Dependence (sociable, attached, dependent) are selectively permitted to develop with no corrective intervention. This raises a question about the role of medicine and psychiatry in “engineering” psychological profiles of young children by “cherry-picking” the favorable profiles and suppressing the unfavorable ones, which is beyond the scope of this chapter. Suffice here to say, biologic adaptation appears to have become less critical for human survival than behavioral and spiritual adaptation. Natural selection is not targeting human morphologic features anymore but rather human personality features and level of awareness. Through its suppression of certain temperament traits and its norm-favoring influence on character development, modern human society appears to have an important role in this process.

Categorical versus Dimensional Approach to Personality Disorder

Medical diagnosis has historically been categorical, and most clinicians tend to “think” categorically for two reasons. First, one of the most important functions of diagnosis is to prescribe appropriate corrective action, that is, treatment. The decision of whether a person is “affected” or “unaffected” (“sick” or “not sick”) is functionally equivalent to the decision whether or not that person needs treatment (hence, categorical diagnosis facilitates treatment decisions in practical work). Second, categorical systems simplify professional communication as they describe prototypical cases that meet all or most of the diagnostic criteria. Just one category, for example, antisocial personality, can communicate a great deal of vivid clinical information about the patient. However, categorical descriptions convey useful information only about prototypical and severe cases but little or no information about atypical, mixed, or mild cases (see later).

Categorical Approach. The categorical approach adopts the medical diagnostic model that a PD is either “present” or “absent” and individuals either “affected” or “unaffected.” Categorical models are optimal for discontinuous variables (e.g., marital status, fractured humerus). However, when distinguishing characteristics of a disorder are variants of normality, such as personality traits, any categorical decision about the presence or absence of a disorder is arbitrary. In other words, one of the major disadvantages of categorical models of PD is that they establish arbitrary cutoff points or thresholds for continuous behavior traits. This becomes clear, especially in mild cases close to the cutoff point, which cannot be well classified neither as “affected” or “unaffected.” In an attempt to minimize this problem, DSM-5 now allows clinicians to classify “maladaptive personality traits” that do not meet the threshold for a PD. Nevertheless, the categorical approach is not optimal for patients who do not perfectly fit their “pigeonhole” in the classification, so an additional wastebasket category for “atypical” or “mixed” cases had to be established, and this often is used to describe most cases of PD. DSM-5 calls this wastebasket “Other specified personality disorders,” but that does not make it more than the wastebasket it was when it was frankly acknowledged to be “not otherwise specified.” Finally, the categorical approach to personality does not even establish a prescriptive relationship between diagnosis and treatment because of the significant overlap of diagnostic criteria for PD subtypes, and categorical systems usually yield multiple personality diagnoses for individual patients. In such cases, treatment decisions and priorities are not easy to establish.

Dimensional Approach. Dimensional models define a number of graded and continuous behavior dimensions and specify individual differences as quantitative variations along these dimensions. These models are optimal for features that vary quantitatively (e.g., as personality does) and have different adaptive significance in different situations. These models account for the fact that everyone has multiple personality traits, more or less prominent and adaptive, rather than being simply present or absent. This eliminates the need for a description of multiple and overlapping categorical diagnoses. By quantifying one's position on a continuous personality trait, dimensional models conserve information about individual patients more than categorical models. Personality dimensions are as easily applied to the common atypical and mild cases as they are to the rare prototypical and severe cases. Finally, by using a dimensional system, one can easily manipulate complex data mathematically and include many variables.

Research has shown that normal personality traits and deviant personality traits observed in PDs represent a continuum where deviant traits are extreme variants of normal, adaptive behaviors. Note, however, that dimensional models do not answer the question of what is it about some traits that make them disorders. Natural breaks or points of rarity on the continuum of normal and maladaptive personality traits have not been detected. The extreme standing alone is not sufficient to be dysfunctional (e.g., people with low Reward Dependence can be well adapted in their environment). Dimensional models have to introduce cutoff points for continuous traits to make them more compatible with categorical diagnoses and thus more useful for treatment decisions or, as proposed here, to use probability estimates for categorical PD diagnosis based on the severity of measured temperament and character traits.

Integrated View of the Importance of Personality Subtypes

There is widespread dissatisfaction with the current official criteria for PD subtypes. The most common clinical diagnosis of PD using DSM-IV was "not otherwise specified." There is no evidence that the putative categories are truly discrete entities that are either present or absent. Should clinicians rely on dimensional or prototypical approaches? Dimensional approaches can consider configurations of scores on multiple dimensions that correspond to particular subtypes of PD. Prototypical approaches allow clinicians to rate the degree to which a particular case matches with the criteria of a particular subtype, now regarded as a prototype or model. What these suggestions ignore is that complex adaptive systems, such as personality, do have moderately stable configurations and that such configurations have modest separation from neighboring conditions. Furthermore, these metastable, quasi-discrete configurations are often maintained by particular gene–environmental interactions that are most predictable when a specific configuration of traits is specified. What is most important is for the clinician to realize that personality subtypes are configurations of component processes that interact as expressions of a nonlinear dynamical system. They are neither discrete taxons nor arbitrary configurations of dimensions. However, they tend to be stable over time which is mostly reflecting the fact that most (but not all) people with PD do not "spontaneously" mature but need professional intervention or some major life events (either extremely good or extremely bad or tragic) to "jump-start" the process. It is useful to recognize traditional subtypes of PD as long as you realize they are metastable, quasi-discrete expressions of complex biopsychosocial processes that are adaptive and dynamic.

In other words, the advantages of categories and dimensions can be combined by a recognition that in complex adaptive systems, it is the configuration of multiple dimensions into a personal profile that determines the functionality of the system. Such multidimensional profiles identify specific individuals with specific characteristics so that they have the advantages of categorical diagnoses without falsely implying that they represent a discrete disorder. For example, a person with antisocial personality is specified in terms of high Novelty Seeking combined with low Harm Avoidance and low Reward Dependence in people with immature character. The person-centered approach to profile analysis provides clusters of people whose biopsychosocial characteristics and behaviors are relatively stable but can be modified by changing circumstances, age, or treatment. Consequently, clinicians are not misled to slip into the fallacies of thinking that PDs are discrete disease entities or that people with a PD cannot change.

Measurement of Personality Disorders

Self-Report or Interview. Interviews are often considered by psychiatrists to be more reliable and valid diagnostic tools than self-reports for measuring PD, whereas psychologists often advocate psychometric testing. In fact, no data for a definite advantage of one of these formats have been established. People, in general, are biased when self-reporting deviant behaviors (in PD, these behaviors are ego-syntonic, perceived as “OK”), so interviewing the patient reduces this problem because unclear, inconsistent, or defensive responses can be clarified, and the patient’s demeanor and appearance observed. On the negative side, interviews tend to be affected by systematic biases, ideologic orientation, experience, and rating idiosyncrasies of interviewers. In self-reports, various response sets (e.g., careless inconsistency, defensiveness, and exaggeration) and validity items can be measured to help in interpretation. Recently, a set of performance scales, independent of the item content, based on the observed regularities in the technical pattern of responding to questions has been defined for validity analysis of the TCI. These performance scales are used to test the validity of self-reported personality traits. Specifically, self-report to questions, regardless of the content of the questions, tends to follow specific patterns that correlate with personality traits. For example, the number of endorsed items that are otherwise rarely found in the general population correlates with low Reward Dependence. These performance scales are used to predict scores on each of the temperament and character dimensions, which are then compared with self-reported, content-dependent scores on these same traits. Substantial score differences between “subjective-” and “performance”-

based scores on personality traits indicate either significant bias or intentional misrepresentation. Training in the use and interpretation of the TCI is available online (https://anthropedia.org).

Both self-reports and interviews depend on the patient's accuracy, honesty, and level of insightfulness. Hence, the collection of data from collateral informants and expert ratings is usually considered critical to ensuring a high-quality personality diagnosis.

State-Trait Effect. Most major clinical disorders have their less severe variants in the form of a PD (Table 26–17). The "state-trait" distinction between symptoms reflecting long-term personality traits and those reflective of transient clinical states can be difficult. Indeed, transient variation in one's emotional state can influence both self-report and clinical evaluation of long-term personality characteristics. The susceptibility to such state effects has been demonstrated for some categorical measures of PD. The state effect can be reduced, although not eliminated when subjects are repeatedly reminded to describe their usual, not their current, behavior, feelings, and attitudes. In contrast to categorical diagnosis, only those dimensions of personality that underlie susceptibility to depression and anxiety, such as neuroticism and Harm Avoidance, tend to covary with mood and anxiety states. Also, increases in anxiety or depression lead to a mild and transient decrease in Self-Directedness and Cooperativeness. Consequently, a person with no enduring PD may act immaturely when depressed or under stress. Self-reports of other dimensional traits, Novelty Seeking, Reward Dependence, and Persistence, in particular, are largely independent of and unaffected by comorbid mood and anxiety states.

Table 26–17.
Phenotypic Similarity between Major Clinical Syndromes and Personality Disorders

Clinical Syndromes: Major Variant	Personality Disorders: Minor Variants	Shared Symptoms
Schizophrenia spectrum	Schizoid PD Schizotypal PD	Negative and positive
Delusional disorder	Paranoid PD	Suspiciousness
Major depression	Depressive PD Borderline PD	Proneness to depressed mood; proneness to self-destruction
Cyclothymia Bipolar disorder Mania	Narcissistic PD Histrionic PD Antisocial PD	Mood swings; impulsivity
Obsessive-compulsive disorder	Obsessive-compulsive PD	Hypochondriasis; inflexibility
Social phobia	Avoidant PD	Shyness; avoidant behavior
Panic disorder with agoraphobia	Dependent PD	Dependency

Categorical Tests for Personality Disorder. The majority of categorical tests for PDs are based on the DSM criteria and share all the advantages and disadvantages of that categorical approach. In the DSM-III field trials, the interrater reliability was 0.61, and the test–retest reliability was 0.54 for any PD. The reliability is usually lower for individual subtypes than for the presence versus absence of any PD because of the difficulty distinguishing among the subtypes. In the DSM-5 field trials, reliability was questionable for most diagnoses, and the reliability for Borderline PD was only 0.34. As a result, the ICD-11 is considering a simpler approach that clinicians can implement more reliably.

Among the **categorical self-reports**, the two most frequently used are The Personality Diagnostic Questionnaire (PDQ R) and the MMPI scales for PD (MMPI PD). The PDQ R is a self-report version of the DSM criteria for PDs, along with the “Impairment/Distress” scale to quantify the significance of impairment or subjective distress required by DSM criteria. In practice, this instrument has been shown to overdiagnose PDs when compared to expert clinical diagnoses.

The MMPI PD scales were derived from the MMPI item pool to evaluate symptoms for DSM-III PDs. The MMPI PD scales are incorporated into MMPI so that, in addition to evaluating PD and other clinical syndromes, clinicians and researchers can also use other MMPI scales (e.g., Lie, Validity, Defensiveness) for validity and response set analyses.

Several semistructured interviews have been developed to diagnose PDs. These typically take more than an hour to conduct, so they have limited use in clinical practice. Among the **interviews that categorically diagnose** PDs, the most commonly used is The Structured Interview for DSM-IV PDs (SIDP IV). The original SIDP was developed for PDs described in DSM-III, and it has been regularly updated with each new DSM revision and edition (SIDP R for DSM-III-R, SIDP IV for DSM-IV). To increase its diagnostic validity, the SIDP-IV requires that answers for selected questions be obtained from a collateral informant. This test can be combined with a 10-minute SIDP-IV screen for PD, which can considerably reduce testing time in populations with many individuals who do not have PD. The screening instrument alone tends to overdiagnose cases but is useful to screen out people with no PD.

Other popular interviews for categorical classification of PDs include the Structured Clinical Interview for DSM-IV PDs (SCID II), The Diagnostic Interview for Personality Disorders (DIPD), and the Personality Disorder Examination (PDE). The PDE is available in an international version from the World Health Organization in several languages and makes diagnoses according to the ICD-10 in addition to DSM-IV. The interviews for DSM-IV PD remain the same for DSM-5 because the official criteria have not changed. There is a questionnaire for the personality trait domains of the alternative DSM-5 criteria called the Personality Inventory for DSM-5 (PID-5), but this involves questions about features that are not sanctioned by either ICD-11 or DSM-5 officially and is based on a restrictive statistical model with assumptions that are no longer plausible.

Dimensional Assessment of Personality Disorders. Historically, personality has been studied and evaluated using dimensions or traits and PD categorically as discrete entities of psychopathology. Hence, conceptual advances in the field of normal behavior and personality have had little or no effect on research in the field of PD and vice versa. For example, if the features associated with Eysenck's model of personality, that is, neuroticism, extraversion, and tough-mindedness, are combined, the resulting combinations do not correspond closely to traditional categories of PD.

The popular Five-Factor Model of normal personality has been recently advocated to account for underlying dimensions of PD as well. However, the ability of the Five-Factor Model to account for the underlying structure of PD has been tested primarily in nonclinical samples and normal individuals. The few studies that tested the Five-Factor Model in clinical samples showed that neuroticism, extraversion, and low agreeableness predict PD symptoms. After controlling for age and depression, only high neuroticism and low agreeableness remained as significant predictors of PD symptoms. These two dimensions define PD in a nonspecific way, namely, as a general predisposition to psychopathology (i.e., high neuroticism) accompanied by an antagonistic behavior facade (i.e., low agreeableness).

Neuroticism also tends to be confounded with nonspecific factors (such as depression or anxiety) that reduce its ability to distinguish PD, other psychopathology (e.g., mood and anxiety disorders), and well-adjusted individuals with high neuroticism, leaving open the question of its specificity for PDs.

In the authors' work, they found that some common core features, distinct from other forms of psychopathology that cause personal dysfunction, characterize PD subtypes classified in DSM-IV and DSM-5 as overlapping syndromes. For example, DSM-IV and DSM-5 arrange all PDs into three Clusters (A, B, and C), each comprising a number of PD subtypes with similar clinical features. Cluster A includes subtypes with predominantly odd and eccentric symptoms (e.g., paranoid and schizoid PD), Cluster B includes subtypes with dramatic, erratic, and impulsive symptoms (e.g., Histrionic, Antisocial, Borderline PD), and Cluster C includes subtypes with fearful and anxious symptoms (Dependent, Avoidant, Obsessive PD). These clusters are suggested to represent three independent clusters of PD subtypes, but empirically the clusters overlap with one another, much as do the subtypes within clusters.

Dimensional tests of PDs are formatted as self-reports (except for Tyrer's Personality Assessment Schedule). The most frequently used are the Millon Clinical Multiaxial Inventory (MCMI), the earlier mentioned NEO PI that evaluates the Five-Factor Personality Model and the TCI that evaluates the Seven-Factor Psychobiological Personality Model. These tests have been originally designed to evaluate normal personality (the NEO PI), psychiatric patients (the MCMI), and both normal personality and deviant personality (the TCI). The NEO PI is discussed previously vis-a-vis the homogeneity of its component traits and its usefulness in clinical work with PD. The other two tests are briefly discussed later.

The MCMI III (designed to match DSM-IV PD categories) evaluates long-term behavior traits systematized as 10 Basic Personality Patterns (dependent, avoidant, schizoid, passive-aggressive, narcissistic, antisocial, hysterical, compulsive, aggressive, and self-defeating) and three Pathologic PDs (i.e., Borderline, Schizotypal, and Paranoid). The latter is used to determine the severity of the 10 Basic Personality Patterns. The test also evaluates nine clinical syndromes. Some reports suggest that MCMI III tends to overdiagnose PD in comparison to expert clinicians.

In the literature, the number of proposed dimensions that underlie deviant personality ranges from 2 to 24 in the literature, although, in most models, it can be reduced to four dimensions (aloof, anxious, anankastic, and adventurous). The optimal number of underlying dimensions and the content of dimensions that purport to describe personality and its disorders most efficiently are still vigorously debated. This ambiguity arises because factor analyses of the behavior of unrelated individuals are always compatible with an infinite number of rotations of the inferred phenotypic factors. Fortunately, recent GWAS have been replicated in multiple independent samples with results that identify unique sets of genes underlying each of the facets of the TCI using a generalized clustering method that does not make arbitrary assumptions about the number of personality factors or their relationships with one another in individuals. In what follows, the distinction between temperament and character is used to improve both the etiologic understanding and the diagnosis of PD. In the treatment section of the chapter, the concepts of temperament and character are used to outline treatment guidelines for patients with PD. First, the TCI is described briefly.

The Temperament and Character Inventory. The TCI evaluates four major temperament dimensions (Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence) and three major character dimensions (Self-Directedness, Cooperativeness, and Self-Transcendence). Each of these main temperaments and character dimensions is composed of component facets (i.e., subscales) to evaluate response patterns elicited by specific stimuli (e.g., Harm Avoidance is observed in different settings as worry and pessimism, and/or fear of uncertainty, shyness, or excessive fatigability). The seven major dimensions and their correlations with the number of symptoms of PDs are shown in Table 26–18. The TCI is a family of tests with several specialized versions designed for varying types of informants (self-report, peer ratings, interviewers), varying age groups (for 3 to 5 years the preschool TCI, 7 to 14 years the Junior TCI, for 12 to 18 years the adolescent TCI, and 15+ years the Adult TCI), scope of information (temperament, character, both), and level of clinical detail (from 60 items for major dimensions only to 240 items for multiple facets of each dimension). The tests for various age groups overlap in their range so that exactly the same test can be administered to a person as they develop across the lifespan. The test measuring the temperament dimensions only was originally called the Tridimensional Personality Questionnaire (TPQ). In the TPQ, Novelty Seeking, Harm Avoidance, Reward Dependence, and Persistence were all measured, but Persistence was originally scored as a component of Reward Dependence. The name of the test was changed to TCI when the character scales were added, and Persistence was recognized as a fourth, separately inherited temperament dimension in twin studies in Australia and United States.

The self-report version of the TCI is a 240-item test available in both true/false and five-point Likert formats. Its psychometric properties are presented in the TCI Manual and online training (anthropedia.org).

Table 26–18.
Correlations between Temperament and Character Inventory Scales and the Total Number of Symptoms for Personality Disorders, Cluster A, Cluster B, and Cluster C

	Total No. PD Sx	Cluster ASx	Cluster BSx	Cluster CSx
Novelty Seeking	0.22[a]	0.02	0.44[b]	–0.06
Harm Avoidance	0.31[c]	0.23[c]	0.08	0.43[b]
Reward Dependence	–0.14	–0.37[b]	–0.08	–0.04
Persistence	0.00	–0.07	0.04	–0.01
Self-Directedness	–0.56[b]	–0.35[b]	–0.43[b]	–0.50[b]
Cooperativeness	–0.44[b]	–0.44[b]	–0.40[b]	–0.28[c]
Self-Transcendence	0.02	–0.08	0.03	0.04

Personality Disorders Inpatients (*N* = 136).

[a] <0.01.

[b] <0.0001.

[c] <0.001.

The ability of the TCI to predict categorical diagnoses of PDs was clinically tested in samples of psychiatric inpatients and outpatients with and without PDs and varying mood and anxiety states. Correlation and regression analyses consistently demonstrate that low scores on character dimensions, especially Self-Directedness and Cooperativeness, are associated with high symptom counts for any PD, for each of the DSM clusters of PD (Tables 26–18 and 26–19), and for each clinical subtype of PD, with or without comorbid clinical syndromes and independent of age. As shown in Table 26–19, the TCI character scales of Self-Directedness, Cooperativeness, and Self Transcendence predict the number of PD symptoms after controlling for age, anxiety, and depression.

Clearly, low scores on character traits represent a core feature (common denominator) of all PD clusters and subtypes.

In differential diagnosis, PD subtypes can be distinguished on the basis of their configuration of temperament scores with little overlap because each subtype correlates with the TCI temperament dimensions in a unique way (Fig. 26–11).

The aforementioned results have important diagnostic and treatment ramifications for PD. Diagnosis is discussed later; the treatment aspects are reviewed in the treatment section.

Table 26–19.
Stepwise Multiple Regression

Total Number of PD Symptoms		
	Partial R^2	***P***
Total number of interview PD symptoms predicted by TCI (controlling for age and depression; inpatients [*N* = 136])		
Age and Depression	0.35	0.0001
Novelty Seeking	—	NS
Harm Avoidance	—	NS
Reward Dependence	—	NS
Persistence	—	NS
Self-Directedness	0.13	0.0001
Cooperativeness	0.03	0.0076
Self-Transcendence	0.02	0.0376
Cumulative R^2	0.18	0.0001
Model R^2	0.53	0.0001
Total number of self-report PD symptoms predicted by TCI (controlling for age, depression and anxiety; outpatients [*N* = 109])		
Age, Anxiety, and Depression	0.45	0.0001
Novelty Seeking	—	NS
Harm Avoidance	—	NS
Reward Dependence	—	NS
Persistence	—	NS
Self-Directedness	0.20	0.0001
Cooperativeness	0.05	0.0001
Self-Transcendence	0.05	0.0001
Cumulative R^2	0.30	0.0001
Model R^2	0.75	0.0001

DIAGNOSIS OF PERSONALITY DISORDERS. Character and temperament traits delineate both the core features and the distinguishing features of PDs (Tables 26–18 and 26–19; Fig. 26–11). Poorly developed character traits, especially Self-Directedness and Cooperativeness, are a common denominator extending across all subtypes of PD as defined in DSM and are used in diagnosis to predict categorical PD symptoms (Tables 26–18 and 26–19). Clinically, low character scores explain chronic difficulties in accepting responsibility, setting long-term goals, fragile self-esteem, and other features associated with low Self-Directedness that are so characteristic of individuals with PD as described in DSM-5. Usually, but not always, these patients are also uncooperative as well (i.e., revengeful, opportunistic, self-centered, socially intolerant, unhelpful to others, and lacking in empathy, compassion, or principles), as is also described in DSM-5.

The combination of high Self-Transcendence with low scores on Self-directedness and/or Cooperativeness correlates with schizotypal and paranoid symptoms (depicting primary process thinking and fanaticism, respectively) and with borderline, histrionic, and narcissistic symptoms (depicting proneness to dissociation), much as predicted in Figure 26–5. In addition, recent data indicate that high Self-Transcendence might be an important component in one's susceptibility to psychosis (when other two character traits are low or, on the contrary, it may predispose to high creativity and well-being (when other two character traits are high). As previously discussed, recent psychobiological studies suggest that the healthiest and happiest people are those who are high in all three character dimensions. Now that the human population's use of resources is exceeding what the planet can replenish, high Self-Transcendence has become crucial if the human species is to avert mass extinction. Human health and survival depend on the cultivation of self-transcendent values and behavior that are altruistic and creative. In addition, the maturity and integration of all three character traits promote physiologic health, happiness, and fulfillment in ways that are indicated objectively by measures of psychophysiological coherence and markers of longevity, such as optimal heart rate variability, vagal tone, and DHEA/cortisol ratio.

High Self-Directedness alone is not always protective against PD. Some narcissistic and antisocial persons can be self-sufficient, resourceful, and successful but still maladapted because of low Cooperativeness (i.e., intolerance of others, revengefulness, low empathy, etc.).

Once the probability for the presence of PD is established on the basis of character, temperament traits are used for differential diagnosis of subtypes. Membership in Cluster A (aloof, eccentric personalities) is most clearly determined by low Reward Dependence (described as social detachment). Membership in Cluster B (dramatic, erratic personalities) is most clearly determined by high Novelty Seeking (described as impulsivity). Membership in Cluster C (anxious, fearful personalities) is determined by high Harm Avoidance (described as fearfulness) (Table 26–20). Other data indicate that Persistence predicts Obsessive–Compulsive traits.

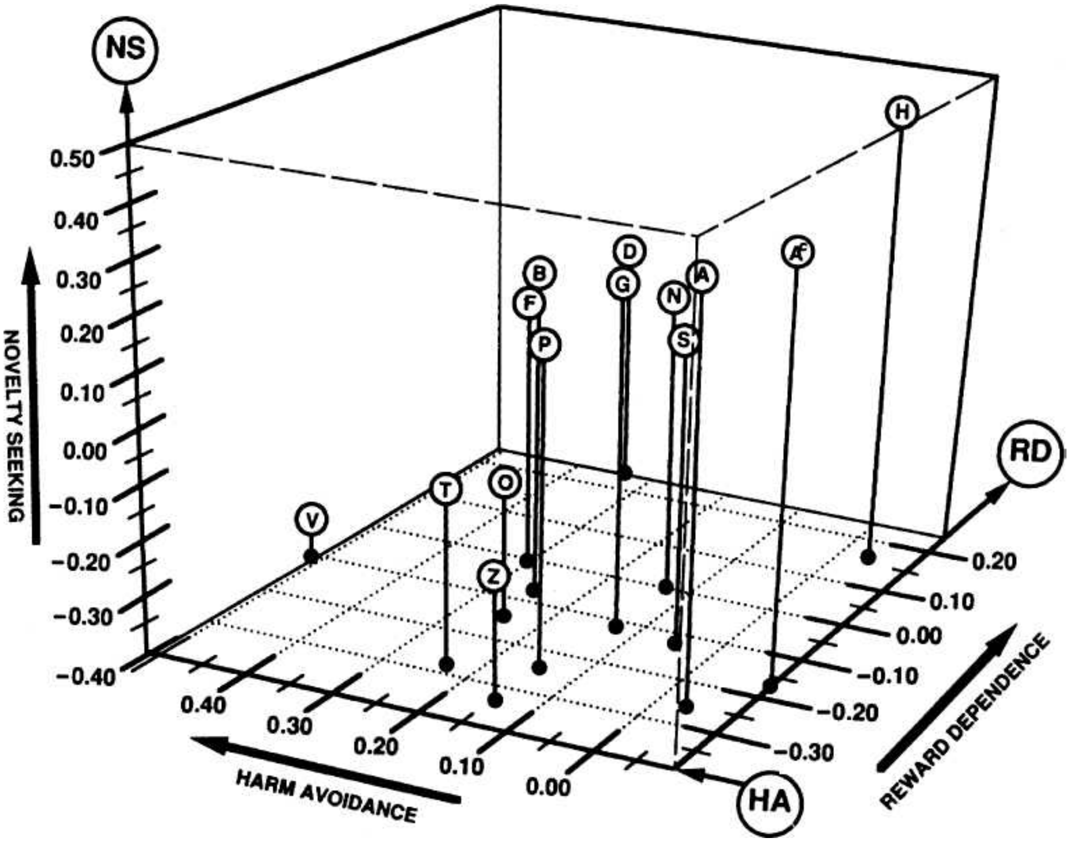


FIGURE 26–11. Correlations between individual PD subtypes and temperament traits of harm avoidance (HA), novelty seeking (NS), and reward dependence (RD). A, antisocial; Ac, antisocial children; B, borderline; D, dependent; F, self-defeating; G, passive-aggressive; H, histrionic; N, narcissistic; O, obsessive; P, paranoid; S, sadistic; GT, schizotypal; V, avoidant; Z, schizoid.

Table 26–20.
TCI Scales and Subscales

I. Temperament:

Harm Avoidance (HA)
- HA1: Worry and pessimism vs. uninhibited optimism
- HA2: Fear of uncertainty
- HA3: Shyness with strangers
- HA4: Fatigability and asthenia

Novelty Seeking (NS)
- NS1: Exploratory excitability vs. stoic rigidity
- NS2: Impulsiveness vs. reflection
- NS3: Extravagance vs. reserve
- NS4: Disorderliness vs. orderliness

Reward Dependence (RD)
- RD1: Sentimentality
- RD2: Sociability vs. aloofness
- RD3: Attachment vs. detachment
- RD4: Dependence vs. independence

Persistence (PS)
- PS1: Eagerness of effort vs. laziness
- PS2: Work hardened vs. spoiled
- PS3: Ambitiousness vs. underachieving
- PS4: Perfectionism vs. pragmatism

II. Character:

Self-Directedness (SD)
- SD1: Responsibility vs. blaming
- SD2: Purposefulness vs. lack of goal direction
- SD3: Resourcefulness vs. helplessness
- SD4: Self-acceptance vs. self-striving
- SD5: Spontaneity vs. lack of congruent second nature

Cooperativeness (CO)
- C1: Social acceptance vs. social intolerance
- C2: Empathy vs. social disinterest
- C3: Helpfulness vs. unhelpfulness
- C4: Compassion vs. revengefulness
- C5: Fairness/principles vs. self-serving opportunism

Self-Transcendence (ST)
- ST1: Self-forgetfulness vs. self-preoccupation
- ST2: Transpersonal identification vs. alienation
- ST3: Spiritual acceptance vs. skepticism
- ST4: Contemplation vs. objectivity
- ST5: Idealism vs. practicality

Individual subtypes of PD are distinguished on the basis of their unique pattern of correlations with temperament traits without any overlap (Fig. 26–11). In other words, the clinical presentation of PD varies along four underlying dimensions, corresponding to the four temperament traits of Harm Avoidance, Novelty Seeking, Reward Dependence, and Persistence (Table 26–16).

The authors' model does not require arbitrary cutoffs for the presence or absence of PD. PD can be quantified in terms of the degree of severity or probability of diagnosis can be estimated. As shown in Table 26–21, the probability for the presence or absence of PD based on the Self-Directedness scores alone ranges from very low (@ 10%) to very high (@ 95%) in clinical samples.

The authors' model "reconciles" some aspects of the categorical and dimensional approach to PD. It specifies seven temperament and character ***dimensions*** to account for individual differences in behavior. These dimensions interact to create temperament and character composites (types, profiles, or configurations), which correspond to **categorical** DSM subtypes of PD (Figs. 26–6 and 26–7). These multidimensional profiles also correspond to the clusters of people with particular profiles of traits associated with sets of genes identified in person-centered GWAS, as noted earlier. In other words, this model is dimensional but still can be used for categorical clinical diagnosis because each temperament and character composite profile corresponds to one clinical category of PD (in practice, this is useful for purposes of description and prediction, of course). These multidimensional profiles are related to underlying causal variables strongly but in complex ways.

Table 26–21.
Predictions of Personality Disorders from Self-Directedness Scores[a]

Self-Directedness Scores	Predicted with PD (%)	Observed with PD	
		f/N	%
44–39	13	4/18	22 ± 0.10
38–34	23	5/17	29 ± 0.11
33–30	33	4/16	25 ± 0.11
29–27	44	8/20	40 ± 0.11
26–23	55	8/19	42 ± 0.11
22–20	66	6/12	50 ± 0.14
19–16	70	14/16	88 ± 0.08
<16	85	17/18	94 ± 0.05

[a] Predicted % = 100 $e^y/(1 + e^y)$, where y = –3.37 +.13 (SD score).

PATHOGENESIS OF PERSONALITY DISORDER

Only a few developmental models of PD are available. Of those, the psychodynamic model focuses on the effects of early traumatic experiences and a constitutionally high disposition to anxiety and anger, whereas the spectrum hypothesis suggests that PDs may be a minor form of particular major clinical syndromes. A growing body of evidence points to nonlinear pathogenesis with multiple factors, including genetic, physiologic, psychological, social, and spiritual influences, which are fully incorporated into the psychobiological model of PD.

The Spectrum Disorder Hypothesis

Echoing Kretchmer’s work from many decades ago, some experts still consider subtypes of PDs as “minor” variants of “major” clinical syndromes. Indeed, some clinical disorders have variants in PDs. For example, Schizophrenia is represented by Schizoid PD, Delusional Disorder by Paranoid PD, Social Phobia by Avoidant PD, Cyclothymia by the group of emotionally unstable Cluster B PDs, and so forth (see Table 26–17).

These disorders are symptomatically similar and frequently differentiated from PDs only by the severity of their clinical presentation. The etiopathogenetic nature of this major-minor relationship has not been established. PDs might be predisposing factors, premorbid features, or subclinical expression of other major clinical disorders. Their common etiology, however, is still an open question. An etiologic relationship has only been supported for Schizotypal personality and the spectrum of Schizophrenia.

Psychodynamic Model of Personality Disorder

The central idea behind this model is that PD subtypes, classified as separate nosologic units, reflect different behavioral expressions of the same core deficit in personality. The so-called “borderline level of personality organization” described by Kernberg has been postulated to represent the nucleus shared by most subtypes of PD.

As defined by Kernberg (1975), the borderline level of personality organization is characterized by ***nonspecific manifestations of Ego weakness*** (such as lack of impulse control, lack of anxiety tolerance, and lack of sublimatory potentials), ***specific Ego defects*** (manifested as partially blurred self-object boundaries, mild to moderate primary process thinking, periodically distorted reality testing), ***partial object relations*** (manifested as alternations between “all good” and “all bad” perception of the self and external objects), ***primitive defense mechanisms*** (centered around splitting), and ***identity disturbance.*** In addition, an inadequately developed Super-Ego is either sadistic (e.g., obsessive personalities) or rigid in some but completely absent in other areas, permitting conflict-free expression of impulses and behaviors.

Immature defenses and a fragmentary self-concept (which are very similar to the above-described borderline personality organization) are a normal early phase in mental development. In the case of PD, however, this early developmental phase pathologically persists in later periods. Etiologically, this pathologic persistence of immaturity is postulated to reflect either constitutional factors (e.g., poor anxiety tolerance, high aggressivity, genetic vulnerability to certain affects) or traumatic environmental factors (e.g., early separation, loss of a parent, physical or mental abuse, neglect).

According to this dualistic theory, because of such traumatic etiologic factors, aggressively charged, negative representations of the self and external objects are predominately incorporated into the internal world. This, in turn, interferes with the crystallization of the early Ego, which normally occurs around positive, libidinally cathected representations of the self and external objects. In other words, normal early motivation and growth are centered around positive primary emotions, particularly interest and joy. The relative predominance of strong negative emotions, particularly anger and fear, interferes with normal character development. As a consequence, primitive defenses (splitting and the related defenses), which are normally predominant in this early phase of life, pathologically persist in the inner world and interfere with normal development. More mature defenses, such as repression, require more energy for their operation than splitting (e.g., repression requires at least as much energy for its operation as is contained in unacceptable impulses). In contrast, splitting keeps opposite “good” and “bad” self and object representations apart from each other. As Kernberg pointed out, splitting and early Ego weakness perpetuate each other. By protecting positive self and object representations, that is, keeping them apart from their negative analogs, primitive defenses ensure at least some development around positive experiences but interfere with neutralization of aggression and fear. These “pregenital” emotions and their related impulses (or a chaotic combination of pregenital and genital ones) persist as dominant motivators of behavior and significantly interfere with normal personality development.

The Borderline Core of Personality Disorder. Kernberg describes the borderline personality organization as follows:

1. Chronic free-floating anxiety
2. Polysymptomatic neurosis (e.g., multiple phobias related to one’s body or appearance, bizarre conversion symptoms, dissociative reactions, hypochondriasis)

3. Polymorphous perverse sexual trends (e.g., the coexistence of genital and pregenital elements, bizarre forms of perversions involving aggression)
4. Poor impulse control and addictions
5. Shift toward primary process thinking (“magical” thinking, primitive fantasies)
6. Partially impaired reality testing

Note, however, that the aforementioned symptoms are not unique to individuals with borderline personality but are shared by other subtypes of PD. Reich and Frances have shown that “the diagnosis of borderline personality organization is essentially equivalent to the diagnosis of PD (any subtype).” Likewise, a hierarchical cluster analysis of identical and fraternal twins, their siblings and parents, showed that 12 DSM PD subtypes can be grouped into eight heritable syndromes, which can be further aggregated into one group closely corresponding to the above-described borderline personality organization.

Perry and Vaillant wrote: “Just as fever, pus, and callus formation are the body’s physiologic reactions to insults of disease, personality disorders reflect persons’ efforts to heal themselves.” Indeed, a PD reflects a person’s attempt to overcome its underlying fragility through purposeful but maladaptive behaviors. These maladaptive behaviors are referred to as “purposeful” because they compensate for the fragility and proneness to decompensation associated with the borderline nucleus. Persons with PD become less fragile because the personality deviation (e.g., narcissism) takes over as the principal motivator of behaviors but more abnormal because an already immature personality is further impaired by additional distortions of self- and object representations.

These compensatory behaviors can have different types of symptomatic setups (e.g., avoidant, paranoid, antisocial, schizoid, dependent). Note that compensatory behavior styles help to classify a syndrome regarding its descriptive label (e.g., avoidant, antisocial) but tell little about the real character of the disorder underlying the descriptive label. Compensatory behavior styles develop as a function of both internal factors (e.g., fearfulness causes avoidant symptoms) and external factors (e.g., social class shapes antisocial behaviors). In other words, depending on certain constitutional and environmental factors, persons with borderline level of personality organization “create” the clinical picture of their PD.

A subgroup of borderline patients manifests the core symptoms, for example, stormy affects, vague identity, unstable relationships in a rather stable way (“stable instability”). These patients are fragile and prone to fragmentation but do not develop any compensatory behavior facade to protect their fragility. Some of them can periodically “mimic” behaviors of any PD subtype (avoidant, antisocial, obsessive) as a temporary, “chameleon-like” solution to their chronic internal problems.

The described compensatory process generates a two-level personality structure with the dominant compensatory self-concept and the split-off real self-concept. Consequently, the clinical expression of PD is dominated by overt, prototypical behaviors, but a set of subtle and covert symptoms and signs associated with the underlying borderline nucleus are regularly observed in the clinical picture. These difficult-to-detect symptoms are overlooked in the DSM system as diagnostic criteria of PD. For example, the clinical presentation of the narcissistic personality is dominated by the grandiose self, a deviant self-concept that generates an unrealistic sense of one's specialness, entitlement, arrogance, and other prototypical narcissistic behaviors (included in the DSM description of this disorder). The hidden real self of a narcissistic person is recognizable through chronic feelings of inferiority, hypochondriasis, envy, and pessimism that are not included in the DSM description of this disorder, even though they regularly accompany and sometimes even dominate the clinical presentation of pathologic narcissism.

Some Conceptual and Methodologic Issues. The borderline level of personality organization can be reliably distinguished from the schizophrenic spectrum disorders but less reliably from affective syndromes. The same immature personality processes that increase the susceptibility to deviant behaviors may also increase the susceptibility to mood disorders. In many cases, mood disorders and PD are comorbid and can be interwoven to the extent that no meaningful distinction between them can be made (as implied in the concepts of depressive personality, hysteroid dysphoria, or characterologic depression).

An increasing number of psychometric tests to improve the reliable measurement of psychodynamic constructs are available (e.g., the Defense Style Questionnaire and the Structural Interview of Personality Organization). Satisfactory diagnostic stability and discriminant validity in patients diagnosed as "borderline personality organization" has been demonstrated.

Both the psychodynamic model and the psychobiological model define a common denominator ("the core feature"), which extends across discrete subtypes of personality syndromes. This core feature is the borderline personality organization in the psychodynamic model and poorly developed character traits, particularly Self-Directedness, in the psychobiological model. Symptomatically, low Self-Directedness and borderline personality organization are for all practical purposes identical. For example, individuals with low Self-Directedness are described as blaming, helpless, irresponsible, unreliable, with no internal direction, and with difficulties in defining and pursuing stable goals (rather, they tend to experience numerous short-term, frequently mutually exclusive motives, none of which can develop to the point of real personal significance). It has been shown that low Self-Directedness correlates highly with the use of immature defense mechanisms that are central in the psychodynamic concept of borderline personality. Etiologically, both concepts postulate that excessive negative emotionality, such as fear and anger (or high Harm Avoidance and high Novelty Seeking), interferes with developmental processes and increases the risk of PD. The psychodynamic concepts can be incorporated into the more comprehensive biopsychosocial understanding of PD based on a solid objective foundation from genetics and functional brain imaging that were not available when the psychodynamic concepts were initially developed.

Psychobiological Summary of Personality Disorder

Psychodynamic understanding of PD, as shown previously, was a useful first step in the understanding of human behaviors. However, the psychodynamic model neither accounts for nor provides directions for expanding the current understanding of the full etiologic complexity of PD. In other words, as an etiologic theory, the psychodynamic model addresses only a portion of the iceberg representing deviant behaviors. As a treatment tool, manualized psychotherapies using different techniques tend to yield remarkably similar benefits, as expected from nearly all the variance in the outcome being attributed to the intersubjective and person-centered qualities of the therapeutic alliance, as discussed earlier. Psychodynamic strategies are an integral part of the comprehensive psychobiological approach to the treatment of PD presented in this chapter, but optimal treatment outcomes depend on effectively addressing all three human systems of learning and memory in order to help people to integrate their habits and skills with meaningful goals and self-transcendent values.

Modern psychobiology of behaviors provides an integrative, multifactorial, and etiologic model of the development of personality and its disorders. The biopsychosocial approach is based on four fundamental perspectives: genetic, neurophysiologic, learning, and phenomenologic that interact in a nonlinear way to produce phenotypic differences in behavior traits, cognitive style, and self-awareness. The psychobiology and sociocultural influences on temperament and character traits are discussed throughout this chapter (see Tables 26–2 through 26–10 for review). The adaptive self-organization of character is discussed in the section on development. Diagnostic and treatment implications are discussed in the corresponding sections. The following section summarizes the biopsychosocial concept of PD.

Multiple genetic and environmental factors interact in complex ways to influence the risk of PD. As a reminder, roughly half of the variance in temperament is explained by over 700 genes, which are nearly all protein-coding genes that mediate behavioral conditioning. It is the complex interactions of multiple genes with one another and with environmental variables, not the average effects of individual genes, that account for variability in personality. These temperament traits determine one's susceptibility to specific neurochemical processes that in turn underlie individual differences in basic emotions and influence early learning characteristics. These temperament traits have distinct genetic, neurobiologic, and phenomenologic correlates (Tables 26–2 through 26–6).

Character represents the higher cognitive processes that allow self-regulation of temperament and is also influenced by many genes, including many regulatory RNA genes that influence intentional self-control and creative self-awareness. These RNA genes regulate the expression of genes that encode proteins so that changes in self-awareness can actually allow a person to modify the expression of the genes the influence their physical, mental, and social well-being. Temperament and character traits reciprocally influence each other, as a person adapts to changes in their internal and external milieu and learns how to express their identity in satisfying and meaningful ways. As shown in Table 26–22, various temperament types affect differentially one's risk of immature character and PD. Some configurations, mostly those with high Reward Dependence, are protective against PD, whereas some increase this risk (e.g., the explosive or borderline profile with low Reward Dependence, and high Novelty Seeking and Harm Avoidance). Contrary to the common belief, average scores on the temperament dimensions do not protect against maladaptation and immaturity. People with average temperament traits have an average (not a decreased) risk of PD (Table 26–22).

Extreme temperament variants are not necessarily indicative of PD. They are expected to be associated with long-term personal, social, and/or occupational impairments that warrant the PD diagnosis ***only when accompanied by inadequate development of the three character traits of Self-directedness, Cooperativeness, and Self-transcendence.*** In other words, poorly developed character is what makes some behavior traits maladaptive and increases the risk of PD. An individual high in Novelty Seeking and low in Harm Avoidance may have an impulsive PD if they are low in Self-Directedness and Cooperativeness, or may be an inquisitive scientist without PD if they develop a creative character (i.e., are well developed in all three character traits). A creative character profile provides the intuitive insight and judgment to have a unifying outlook on life characterized by understanding the virtues of hope (i.e., Self-directedness), love (i.e., Cooperativeness), and faith (i.e., Self-transcendence), which leads to physical, mental, social, and spiritual well-being. In contrast, individuals who are emotionally reactive have an unconscious outlook of separation characterized by fear, unmet desires, self-doubt, and shame (sometimes compensated by vanity). Intermediate between these extremes, individuals with organized character profiles (i.e., high Self-directedness and Cooperativeness but low Self-transcendence) are individualistic and materialistic, seeking to maximize their wealth, power, and fame without recognition that their lack of identification with other people and the world is ultimately self-defeating because their struggles and desires are insatiable.

Table 26–22.
Relative Risk of Personality Disorder as a Function of Temperament Type in a Sample from the General Community

Temperament Type	Configuration	*N*	Immature (%)
High risk			
Borderline	NHr	39	72
Obsessional	nHr	44	59
Antisocial	Nhr	25	48
Passive–aggressive	NHR	30	40
Average risk			
Average profile	—	15	33
Low risk			
Avoidant	nHR	30	17
Schizoid	nhr	31	16
Histrionic	NhR	50	12
Reliable	nhR	36	6
Total		300	33

Lower case letters (h, n, r) and capital letters (H, N, R) indicate low and high values for temperament traits.

The concepts of temperament and character are essential to decompose the symptoms of PD into the ***common features*** shared by all PDs, and ***distinguishing features*** that permit the discrimination among PD clusters and individual subtypes. This is not possible for models that confound temperament and character. This also indicates that PD reflects deviations in both temperament and character, that is, in both emotional and conceptual personality processes.

Emotionally reactive individuals with little character development are often diagnosed with PDs. Such individuals have low physical, mental, and social well-being, but this may still represent a point of developmental stability for many individuals, even though it is a suboptimal level of adaptation. Such suboptimal outcomes, which are clearly maladaptive relative to the possible maximum for that individual, tend to be stable. The resistance to change of suboptimal personality configurations occurs because substantial improvement in well-being often requires a person to give up immediate gratification in order to achieve something of greater ultimate value (e.g., a cocaine addict giving up cocaine in order to establish a responsible and sober life). Therefore, growth in personality and well-being requires much more than the conditioning of habits and skills or advice about healthy goals; personal growth in well-being depends strongly on growth in self-awareness and particularly in self-transcendence so that a person can imagine their future in vivid detail and commit to achieving their valued goals with perseverance.

Behavior genetic research has demonstrated the importance of gene–environment interactions in personality development. For example, prospective studies of birth cohorts in Finland have demonstrated that specific genetic variants of the dopamine DRD2 and DRD4 receptor influence the development of Novelty Seeking but only in individuals exposed to harsh and inconsistent discipline by emotionally distant parents. Behavior geneticists have demonstrated that the effect of sociocultural factors on personality appears less specific than that of genetic factors, influencing success in adaptation rather than its form or personality style. Hence, psychosocial disorganization in the rearing environment of a child has a substantial influence on the risk of PDs. This is essential for preventive strategies as even temperament configurations with a high risk of PD might be overcome in homes and communities that provide security and limits on behavior in a warm, compassionate manner, as well as encouraging self-directed choice and the value of respect for other people.

PD is associated with younger age. This indicates maturation (i.e., remission of deviant behaviors) with increasing age. In general, three dimensions of personality change substantially with age. Novelty Seeking decreases with age by approximately 18% so that older individuals become less impulsive (more reflective), less rule-breaking (more orderly), and less quick-tempered (more stoical). Cooperativeness increases markedly in most children during school age and then increases by 12% on average after the age of 18 years. Self-Directedness increases markedly in most people during adolescence and young adulthood, increasing on average by 9% after the age of 18 years. Prospective studies with four measurements from the ages of 20 years to 45 years show that Self-Directedness and Cooperativeness increase substantially with increasing age, whereas Self-Transcendence decreases between the ages of 20 and 45 years before increasing again as people must face ultimate situations like their own mortality.

The decreasing prevalence of PD with age is attributable to the increased development of both Self-Directedness and Cooperativeness with age. The additional tendency for Novelty Seeking to decrease with age explains the finding that patients with impulsive PDs show more improvement than those with anxious or eccentric PDs. The best-documented finding of a change in deviant behaviors is the remission of criminal behavior in individuals with Antisocial PD, which usually occurs if and when they get a good job, find a loving spouse, or experience a spiritual conversion. These individuals nearly always remained impulsive (high Novelty Seeking), risk-taking (low Harm Avoidance), and aloof (low Reward Dependence) but became mature enough to maintain work and family life in a stable and sober manner.

TREATMENT

Stages in the Development of Self-Awareness and Well-Being

A full assessment of personality requires consideration of a person's level of self-awareness and well-being, not just their impairments. Health and well-being are more than the absence of deviant traits. Well-being depends on a person's level of self-awareness and leads to the expression of human virtues and positive emotions that go beyond what is average in contemporary society.

There are three major stages of self-awareness along the path to well-being, as summarized in Table 26–23, based on extensive work by many people. The absence of self-awareness occurs in severe PDs and psychoses in which there is little or no insightful awareness of the preverbal outlook or beliefs and interpretations that automatically lead to emotional drives and actions. Lacking self-awareness, people act on their immediate likes and dislikes, which is usually described as an immature or "childlike" ego state.

The first stage of self-awareness is typical of most adults most of the time. Ordinary adult cognition involves a capacity to delay gratification in order to attain personal goals but remains egocentric and defensive. Ordinary adult cognition is associated with frequent distress when attachments and desires are frustrated. Hence, the average person can function well under good conditions but may frequently experience problems under stress. At this stage of self-awareness, a person is able to make a choice to relax and let go of their negative emotions, thereby setting the stage for acceptance of reality and movement to higher stages of coherent understanding. Therefore, patients who are disturbed by negative emotions and unmet desires can be taught to practice various skills for relaxation to help them enter the first stage of self-awareness. There are a wide variety of effective relaxation techniques, including deep and slow abdominal breathing to activate the vagal nerve, one-pointed concentrated meditation increasing vigilance, nature walks or listening to harmonious music.

Table 26–23.
Three Stages of Self-Awareness on the Path to Well-Being

Stage	Description	Psychological Characteristics
0	Unaware	Immature, seeking immediate gratification (“childlike” ego state)
1	Average adult cognition	Purposeful but egocentric; able to delay gratification but has frequent negative emotions (anxiety, anger, disgust) (“adult” ego state)
2	Metacognition	Mature and allocentric; aware of own subconscious thinking; calm and patient, so able to supervise conflicts and relationships (“parental” ego state, “mindfulness”)
3	Contemplation	Effortless calm; impartial awareness; wise, creative, and loving; able to access what was previously unconscious as needed without effort or distress (“state of well-being,” “soulfulness”)

Adapted from Cloninger CR. ***Feeling Good: The Science of Well-Being***. Oxford University Press; 2004:219–225.

The second stage of self-aware consciousness is typical of adults when they operate like a “good parent.” Good parents are allocentric in perspective—that is, they are “other-centered” and capable of calmly considering the perspective and needs of their children and other people in a balanced way that leads to satisfaction and harmony. This state is experienced when a person is able to observe their own subconscious thoughts and consider the thought processes of others in a similar way to observing their own thoughts. In this state, a person is interested in understanding their thoughts without judging or blaming, which requires that they are already in a state of relaxation and acceptance. Hence, the second stage is described as “metacognitive” awareness, mindfulness, or “mentalizing.” The ability of the mind to observe itself allows for more flexibility in action by reducing dichotomous thinking. At this stage, a person is able to observe himself and others for understanding, without judging or blaming. However, in a mindful state, people still experience the emotions that emerge from a dualistic perspective, so mindfulness is only moderately effective in improving well-being.

The third stage of self-awareness is called contemplation because it is the direct perception of one’s initial perspective—that is, the preverbal outlook or schemas that direct one’s attention and provide the frame that organizes one’s expectations, attitudes, and interpretation of events. Direct awareness of one’s outlook allows the enlarging of consciousness by accessing previously unconscious material, thereby letting go of wishful thinking and the impartial questioning of basic assumptions and core beliefs about life, such as “I am helpless,” “I am unlovable,” or “faith is an illusion.” In other words, contemplation is a reversal of the process of repression: contemplation enlarges consciousness, whereas repression reduces it. The third stage of self-awareness can be described as contemplative because, in this state, a person becomes aware of deep preverbal feelings that emerge spontaneously from a unitive perspective, such as hope, compassion, and reverence. To enter this state from mindfulness, a person begins to recognize that their perceptions may be biased by unconscious information so that they can begin to examine and question what they had previously assumed to be an impartial perspective. Contemplation is much more powerful in transforming personality than is mindfulness, which often fails to reduce feelings of hopelessness because it allows enlargement of consciousness to provide a broader perspective for flexible, prosocial, and creative adaptation.

Extensive empirical work has shown that movement through these stages of development can be described and quantified in terms of steps in character development or psychosocial development, as in the work of Vaillant on Erikson’s stages of ego development. As previously mentioned, such development can be visualized as a spiral of expanding height, width, and depth as a person matures or increases in the coherence of personality. Likewise, the movement of thought from week to week or month to month has the same spiral form regardless of the timescale. Such “self-similarity” in form regardless of timescale is a property characteristic of complex adaptive systems, which are typical of living processes in general, whether they are psychosocial or neurobiologic. The clinical utility of this property is that therapists can teach people to exercise their capacity for self-awareness, moving through each of the stages of awareness just described. Their ability to do so, and the difficulties they have, reveals the way they are able to face challenges in life. Cloninger has developed an exercise called the “Silence of the Mind” meditation, with explicit instructions to take people through each of the stages of awareness as well as they can. The first phase of this meditation results in a relaxed state in the first stage of self-awareness. The second phase facilitates entry into the second stage of self-awareness, and the third phase into the third stage of self-awareness, if the person is able to do so. Using this and a way of observing thought during the mental status examination, mental health professionals can assess a person’s thought and its level of coherence in a way that is constructive, easy, and precise without being judgmental.

Each step of growth in self-awareness and well-being requires particular psychobiological conditions. The emotional dynamics of growth in well-being are depicted in Figure 26–12 as a transition within a nonlinear dynamical system. The transition from one state of lower well-being (state A) to a state of higher well-being (state B) requires growth in self-awareness. Each such transition requires a person to accept the limitations of the assumptions they have been making about what is satisfying and valuable in order to begin adapting in ways that are more coherent and flexible. However, such growth requires a person to let go of what is familiar that so there is a temporary increase in negative emotions before there is further growth in positive emotions and other aspects of well-being. Therefore, an effective clinician must help provide appropriate conditions to facilitate this transition ("the energy of activation") with their own compassion, hope, patience, and awareness, realizing that the patient must ultimately be the one who does the work to grow in self-understanding from an outlook of separation with frequent negative emotions and self-defeating behaviors toward an outlook of unity with frequent positive emotions and self-actualizing behaviors. Each step along the pathway to well-being requires different procedures to facilitate growth because different aspects of the being are involved in the different steps in character development. These specific techniques for the various steps in development are described in what follows.

General Principles of Treating Personality Disorder

At the outset of treatment of PD, and as a general principle, the psychiatrist should establish compassionate but professional boundaries while seeking a healthy and strong working alliance with the patient. The psychiatrist should endeavor, as often as possible, to be clear, concise, and consistent in the face of the many unconscious and conscious attempts to derail a healthy treatment process that can occur when working with individuals struggling with PD. Less is often more unless responding to an acute crisis situation (discussed later in this chapter) and, even in the acute crisis situation, the psychiatrist must guard against overreaction and catastrophizing, creating an appearance to the individual of the potential for "giving-up" on the patient. The psychiatrist working alone will have to navigate the challenges of being both a "good object" and "bad object" while retaining a consistency of approach, reality testing where appropriate, and maintaining the therapeutic alliance. The risk of boundary issues and burn-out can be mitigated by the use of a consultant or supervisor to reflect regularly on the case. Alternatively, creating a team approach can also help to avoid these pitfalls.

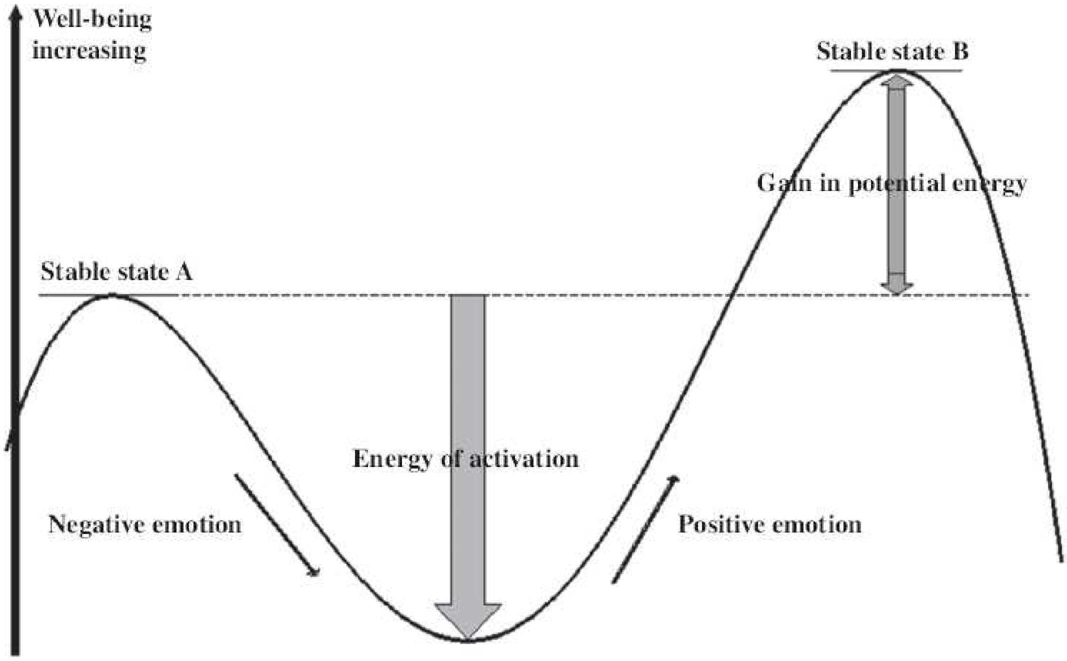

FIGURE 26–12. The emotional dynamics of well-being as successive transitions in a complex adaptive system. (Used with permission of Anthropedia Foundation.)

In general, the undertaking of the treatment of PD is most effective when the psychiatrist is part of a highly coordinated team. This may include therapists, primary care physicians, a well-being coach, close family members, and other specialist practitioners. This provides the surest way to avoid making the most common errors such as those that arise from countertransference issues (discussed later in this chapter), supports consistency in reinforcing boundaries, and aids in a creative person-centered treatment response by having “many pairs of eyes” on the situation. Treatment of PD should be approached as a “marathon,” not a “sprint,” and building a care team and support network allows for greater longevity in the treatment approach. A strong emphasis on coordination and communication among the team allows for the consistency of this approach. Therefore, at times it may require that up to 80% of the time and energy devoted to helping an individual with PD is spent “backstage” coordinating with the support network, with the remaining 20% in front of the individual. However, this will change over time as the team grows in its confidence to provide clear, concise, and consistent communication with the patient, who is at the center of this treatment process. Third-party payer systems often do not reimburse for time spent in care coordination, and thus increasing numbers of psychiatrists choose to opt out of insurance systems in the interest of optimal care.

Medication is only one of many tools that will be used by the psychiatrist in the treatment of PD. The array of symptoms and comorbid disorders means that there are multiple pharmacologic options that may be considered (discussed in more detail later in this chapter). However, it is important to keep some general principles in mind when prescribing for patients with PD. Medication can often become a kind of “transitional object” for the immature personality, and as such, the psychiatrist must try to avoid making medication the entire focus of treatment or building the therapeutic relationship solely around prescribing. This only enables the avoidance of addressing and prioritizing what the patient (and clinician) may see as the more difficult challenges, such as self-regulation, goal setting, and expansion of self-aware consciousness. Psychiatrists can all too easily be seduced into focusing on what they see as the “easier” or concrete issue of dosages and medication compliance, unintentionally cultivating dependence and undermining the development of autonomy and responsibility, which are at the foundation of long-term sustainable change in PD. On the other hand, by holding the patient accountable for the reasonable and responsible use of a medication regimen, one that they can take ownership of, medication will be part of the overall maturation of the individual.

Another common challenge in the use of medication in PD, resulting from the presence of multiple comorbidities, is the frequent use of poly-pharmacy and all the inherent risks it presents. Again, if approached in a person-centered way, this can be an opportunity for building responsibility by both complex reconciling regimens and creating ways for the patient to be accountable for compliance.

The work of Zwir, Cloninger, and colleagues on the underlying genetic architecture of personality helps to orient the treatment process around some general principles of character maturation involving stages of learning. During the “emotional-regulation” phase, the patient may need “containment” and strong boundaries but will also benefit from the consistency of the individual treatment setting and/or the unity of the treatment team. By receiving clear and consistent messages, with “everyone on the same page,” the patient is better placed to experience the satisfaction of moderating their own emotional responses and diminishing the use of primitive defenses such as splitting. While the patient may initially try to project their own outlook of separation onto the psychiatrist or the clinical team (e.g., all nurses are treated as “good” and all social workers are treated as “bad,” or vice versa), diligence and/or team work, presenting a concise unified message, will extinguish much of this behavior and often remarkably quickly. The psychiatrist, sometimes viewed as an “authority figure,” is critical in the process of building team cohesiveness and coherence. The so-called “third-wave” cognitive therapies, such as Dialectical Behavioral Therapy (DBT), may also be incorporated as part of the treatment plan for this phase of development.

During the “self-control” phase, the use of coaching techniques and a person-centered approach will help the patient take ownership of their treatment plan through accountability, goal setting and following through on daily objectives, working in the service of others, building empathy, and cultivating a more allocentric outlook rather than egocentricity. With this, the “victim” tendency of the patient begins to diminish, and with frequent positive feedback, the patient beings to grow in hope and motivation for recovery.

During the "self-awareness" phase, the patient is helped to gain perspective. This can come from a wide variety of sources. The use of narrative therapy, time in nature, meditation, and acting in awareness of our interconnectedness with the universe all help to give the patient a greater sense of purpose and helps the patient to grow in free will. The well-being coaching program created by the Anthropedia Foundation is a rare and unique example of an internationally validated, cross-cultural program that specifically addresses self-transcendence and offers concrete tools to cultivate growth in awareness as well as growth in character more generally. Such a program could be usefully integrated into a team approach when addressing this phase.

It is of utmost importance for the psychiatrist to recognize that these treatment "phases" are stages of learning and, like the stages of change (Transtheoretical Model of Prochaska and DiClemente) or the stages of self-awareness discussed earlier (Biopsychosocial Model of Cloninger), are not a simple linear progression. Rather, the psychiatrist must see them as part of an upwards "spiral" of growth. Each phase is interconnected, and the treatment emphasis may move from one to the other and back again as the patient experiences maturation of character and growth in self-control. An upwards spiral means a return to the "same place" will be a frequent and inevitable feature of progress. It is crucial to point out to the patient, and the clinical team, that this is not back to "square-one" but a return to familiar challenges with an incrementally elevated perspective and an opportunity to make new and more satisfying choices. The feelings of emptiness and powerlessness, so common in PDs, can markedly diminish when the patient understands and appreciates this upwards journey and the incremental improvements in problem-solving abilities that accompany it.

To partially summarize the general principles of treating PD, we can turn to an inspiring quote sometimes attributed to Plato. "Be kind, for everyone you meet is fighting a hard battle." The psychiatrist needs to seek all possible ways to remain kind in the face of what can sometimes be overwhelming despair on the part of the patient. Team support, consistent boundaries, clear communication, and a person-centered approach using the multiple available therapeutic tools will all help the clinician to remain calm and compassionate and to stay the course. Above all, however, the psychiatrist must retain perspective; everyone is struggling, and it is a hard battlefield. The psychiatrist is on their own path to well-being and can use the challenges of therapy with patients who have disordered personalities as a stimulus for their own growth in humility, compassion, and expansion of awareness. The rise in the prevalence of psychopathology of personality, which has become perhaps the dominant clinical challenge of our time, cannot be separated from the rise of an individualist consumerist society that encourages unlimited desire and celebrates the hubris of unregulated self-expression that treats others as objects to be controlled. When considering the maturation of a personality in such a chaotic environment, it seems perhaps remarkable that humans are able to find joy and wisdom at all, and thus we can marvel at the dignity and inspiration of the natural tendency for growth and self-actualization present in every human being.

Primary Pathology and Secondary Symptoms of PDs

A common assumption is that pharmacotherapy impacts only the biologic aspect and psychotherapy only the psychological aspect of the human being. However, psychotherapy can modulate structural CNS characteristics, such as receptor activity and expression, through epigenetic mechanisms. Likewise, pharmacologic treatment of depressed mood or symptoms of psychosis can restore complex psychological functions, such as integration of identity. Some might consider it ironic that the strongest evidence for the effectiveness of psychotherapy comes from biologic neurosciences.

However, pharmacotherapy is not a substitute for psychotherapy because taking medication does not involve learning, although it may provide stabilized conditions that facilitate learning. For example, medications can be helpful in modulating anxiety or aggression but not in enhancing self-awareness or inter-subjective awareness. Unstable mood, intensive but unstable interpersonal relationships or risky and self-destructive behavior can be prominent symptoms observed in patients with PDs, but they are non-specific and secondary complications of the underlying problem that needs to be treated. Fortunately, the recent advances in deconstructing the complex structure of learning systems underlying human personality can now inform and guide treatment for PD.

Preventable Errors in Treating Individuals with Personality Disorders

There are three major barriers to effective treatment of PD, but all are preventable errors within the control of the health care provider. The first is the frequent loss of professional objectivity, signaled by the development of strong emotions (positive or negative) and called positive or negative countertransference. This inappropriate personal involvement is a red flag to reassess diagnosis and treatment. Frequent discussions and counseling with colleagues are useful because even strong countertransference feelings sometimes persist unrecognized.

The second preventable error in PD management is to believe the myth that PDs cannot be treated effectively. This myth is partly generated by countertransference problems of some professionals and then sustained by a failure to consider facts showing the effectiveness of treatment. Belief in the untreatability of a patient creates a self-fulfilling prophecy. For example, many controlled studies indicate that even severe PDs, such as borderline or antisocial

PDs, can be effectively treated with an appropriate condition, such as a cooperative therapeutic alliance.

The third preventable error in PD management is to give direct advice on personal and social problems. This is counterproductive in patients with PD because they usually become dependent, noncompliant, or resentful. Occasionally, direct advice may be offered to some antisocial, narcissistic, and schizoid patients who are at low risk of developing dependency and need precise structure and direction initially. However, it is most beneficial to provide guidance and support without giving direct advice. All that is usually required in supportive therapy is compassionate attention, respect for the dignity of other human beings despite their flaws, and reinforcement of the patient’s existing coping mechanisms that are adaptive.

When tempted to give direct advice to patients, remember that change in personality requires more than common sense and logic. If the relationship leads to frequent advice-giving, then referral to a psychiatrist or a psychologist may be indicated. People change if they become self-aware, usually from personal recognition of dissatisfaction with themselves and their relationships. Personal growth thus arises from new insights about oneself and the environment. Direct advice robs the patient of the opportunity to develop new insights and to learn from their mistakes. In summary, supporting these patients involves joint evaluation of options and encouragement to practice skills in solving problems.

Substantial personality change, which is invariably needed by people with PDs, involves an extensive growth in self-awareness and character development, which requires precise diagnostic analyses, specific treatment strategies, and expert training. The expert treatment may include any of the several available psychotherapy approaches and is usually combined with pharmacotherapy. The major points relevant to psychotherapy and pharmacotherapy of PDs are summarized later.

As already mentioned, individuals with PD have a peculiar capacity to elicit strong emotions from other people. They are often described as aggravating, unlikable, difficult, or bad. Alternatively, they may be seductive or dependent and elicit inappropriate emotions or actions, such as sexual interest or the urge to rescue. Even professionals may have difficulty treating them with respectful objectivity because of a blurring of personal boundaries. Such loss of objectivity occurs because the patient’s deeply felt assumptions about other people may often elicit interpersonal responses that are appropriate to the patient’s assumptions. People’s assumptions about themselves and others often become self-fulfilling prophecies because of automatic mechanisms of affect transfer. If someone smiles at you, communicating appreciation, it is natural to experience feelings of social attachment and to smile back automatically. Likewise, if someone frowns, communicating anger, it is natural to feel defensive in preparation for their angry attack. For example, many patients with PD are suspicious and hostile about others' motives. This distrustful attitude is communicated in many verbal and nonverbal ways and often elicits disagreement or frank hostility from others. These uncooperative responses reinforce the original negative assumptions of the patient, which in turn leads to further alienation.

This vicious cycle of affect transfer can be interrupted only by professional objectivity combined with patience and compassionate respect for the patients' disability. Such objectivity arises from recognizing the overall meaning and implications of their pattern of interpersonal signals so that their verbal and nonverbal communication takes on diagnostic and therapeutic, rather than personal, significance. However, objectivity and empathy are not sufficient and leave the therapist vulnerable to burnout with difficult patients. The necessary patience and compassion require that the therapist has developed their own awareness, including self-transcendence so that they can identify with the other without suffering when the other acts in maladaptive ways. In optimal therapeutic relationships, physicians should be compassionate, hopeful, and patient, and the person in treatment need only be able to identify something of value to seek from their treatment. Whenever professionals become aware of strong positive or negative emotions toward a patient (the so-called "countertransference" reactions), this should help alert them to the possibility that the patient has a PD and/or that the therapist has an opportunity to develop greater insight too, which can be extremely valuable. It is important to remember that both patient and therapist are learning in therapy because of the inter-subjective nature of an effective therapeutic alliance.

As many patients with PD do not recognize or admit their psychopathology, they resist and resent psychiatric diagnoses and any form of mental health treatment. Accordingly, it is prudent to let the patient define their treatment goals and then jointly evaluate the likelihood of successful outcome until treatment goals that both patient and the therapist agree upon can be identified. Initially, these goals should be as simple and concrete as possible (e.g., "to develop social skills" or "to reduce alcohol use"). In many but not all cases, successful completion of this initial phase will motivate the patient to define other, more complex treatment goals and to continue treatment.

A psychiatrist should keep in mind that there is a natural succession of stages in the treatment of patients with PDs. Each has different goals and requires different methods. The complete psychiatrist should be prepared to guide the patient along these stages, ever ready to advance to the next stage if the patient is interested and prepared to do so.

Four Major Stages in Treatment of Personality Disorders

The four stages in the treatment of a patient with PD can be described as (1) crisis management and stabilization, (2) awakening of a positive perspective and personal values in life, (3) other-centered awareness, and (4) integrated intelligence. The initial stage of crisis management and stabilization deals with the presenting problem and stressors in order to help the patient get into a calm enough state and a working alliance with the psychiatrist. The second stage involves elevating a person's outlook on life so that they can experience things they enjoy and value under relaxed conditions. In addition to establishing a trusting therapeutic alliance and a safe context in which a person can face their fears and other difficulties with realistic acceptance, the second phase involves an initial spiritual awakening that has often been neglected in strictly cognitive-behavioral or psychodynamic approaches but without which there is little capacity for fundamental change in the quality of life. The third stage of metacognitive (other-centered) awareness involves increases in self-awareness and capacity for contemplation that elevate a person's usual thoughts, feelings, and relationships in a wide range of conditions. The fourth stage of integration of reason and love in action allows a person to be mature and happy even under conditions that were previously stressful.

During most of the 20th century, many people were doubtful that people with PD could really get well. It was assumed that genetic predispositions and memories of past neglect or trauma were rarely transformed, so the improvement was limited to better defenses and coping strategies. Now research and treatment document that fundamental and lasting growth in insight and well-being is possible when a person is able to recollect their past and imagine options for their future vividly in self-awareness. The past can be reprocessed from a perspective of deeper insight, which gives reality a fresh and more hopeful meaning. People can and must create their own health in each moment, just as our memories are not immutable. Rather they are constantly reconstructed and reimagined as a living interpretation of reality. What we remember or imagine can be felt and reexperienced from different points of view without distorting reality, as occurs when listening to an unfolding narrative or a joke's punchline. Both humor ("ha-ha") and insight ("ah-ha") involve shifts in perspective that evoke a reintegration of feelings and thoughts with new meaning. Likewise, patients with PDs can pass through the natural stages of increasing awareness and insight on their own (i.e., remit spontaneously) or be guided through these stages in treatment facilitated by a scientifically designed set of physical, personal, social, cognitive, and spiritual exercises.

A General Approach to Psychotherapy for Personality Disorder

A useful approach at the initial stage of treatment is to focus primarily on the chief complaints that bring them to treatment. These complaints are often related to a person's work, relationships, and/or general health, which often offer an adequate basis for the diagnosis and initial treatment of PD. For example, a systematic focus on a person's work, school performance, or relationships can identify attitudes, feelings, and behaviors that help them recognize the barriers to their success and happiness. However, this can bring up many sensitive issues that they prefer to minimize or ignore or that lead them to lie and distort information about their real situation.

An alternative initial approach, particularly if they are entering treatment at the request or demand of someone else, is to focus on healthy lifestyle choices, which provides a non-threatening basis for the evaluation of a patient's goals, values, habits, and skills (i.e., their personality). Choices about diet, weight control, exercise, smoking, drinking, and ways of relaxing and managing stress are appropriate for discussion with one's physician and do not threaten or stigmatize the patient. Discussion of these choices with a patient can provide a guiding stimulus for developing more self-direction and constructive planning about life. Discipline in working toward chosen goals is an indicator of maturity. Success in accomplishing even simple goals builds self-confidence and often generalizes to other forms of self-directedness. Lack of success stimulates learning about goal setting and personal growth by, for example, breaking a problem into smaller steps to be taken one at a time. In this process, patients have the opportunity to learn from experience, which is essential for patients with PDs. In many cases, such goal setting and problem solving lead to the ability to admit faults and to recognize one's strengths and limitations. Respect for one's self from accomplishment requires acceptance of responsibility and leads to a trust of others. Self-respect and respect for others usually progress hand in hand. Such patient guidance is a simplified and non-threatening form of what is usually called cognitive-behavioral therapy (CBT) and can be safely practiced in a busy office practice with short but regular sessions.

Growth in self-awareness (i.e., increase in insight and judgment) is possible only once a person is calm enough to face and accept unpleasant realities about themselves. As a result, therapy usually proceeds by a series of small steps that lead to progressively more mature and integrated ways of viewing and coping with the challenges of life. Figuratively speaking, a person who feels fearful, hungry, and rejected cannot appreciate beauty and wonders while struggling to gratify basic needs for safety, food, and comfort. However, if they attempt to meet their most salient in ways that are inconsistent with health-promoting values, thoughts, and habits, then they are acting in a self-defeating manner. Consequently, it is difficult to specify the necessary or sufficient condition for the progress of any particular person because both internal and external resources need to be considered to identify a way to work toward personally valued goals that will promote increasing plasticity, virtue, and health.

There are no procedural recipes that assure treatment outcomes because growth in self-understanding depends on the dynamics of nonalgorithmic processes such as insight, judgment, and creative foresight. What a person desires depends as strongly on their worldview as on their external circumstances. A person’s worldview influences what they find important, meaningful, and satisfying. For example, one person may react to a disaster with posttraumatic stress, whereas another finds meaning in the opportunity to help others, thereby growing in self-awareness and well-being. In fact, internal psychological resources, rather than external material and social supports, satisfy a person’s needs to an increasing degree as they mature. People with PDs have limited internal psychological resources, so their psychotherapy must begin to awakening values that will promote well-being and a willingness to work for greater self-understanding.

What clinicians can do to guide their practice is to understand the three processes that provide the means to healthy personality development and the activities that activate those processes. As mentioned in the introduction, the three basic processes that interact in increasing well-being in everyone are (i) plasticity (i.e., the ability and willingness to change), (ii) virtue (i.e., having intuitive insight into what is good for yourself and others), and (iii) creative functioning (i.e., being innovative, resourceful, purposeful, and responsible so that our habits become congruent with our goals and values). The cultivation of self-awareness and eventually self-transcendence by these three processes provides a pathway that people can follow with freedom and flexibility with available resources and help at their own pace in order to develop a life that is healthy, happy, and good.

People are unlikely to work to achieve goals that they are uninterested in personally. Therefore we encourage people to explore what they value through reflection and meditation on the subject and to consider how much they act on what they value most in their daily lives. Modern lifestyles have put far too great an emphasis on things that are not satisfying or beneficial to the detriment of our health and well-being. Consequently, it is crucial for our own well-being to practice activities that most, if not all people, find effective for cultivating the expression of virtue in their lives. When people are uncertain about what they find satisfying and valuable, they can be invited, as an initial experiment in understanding well-being, to practice living in ways characteristic of people with high levels of well-being. People with creative characters (i.e., who are high in Self-directedness, Cooperativeness, and Self-Transcendence) have the highest levels of well-being. Regardless of their initial personality configuration, most people find it satisfying and beneficial to practice acts of love, hope, and faith, much as is described in positive psychology with acts of kindness or gratitude, because this stimulates people to realize what they personally value. These virtuous practices are broadly described as (1) working in the service of others (e.g., practicing acts of kindness, which expresses an understanding of love), letting go (e.g., letting go of resentments and fights with one’s self and others, which expresses an understanding of hope), and growing in awareness (e.g., acts of faith about what is not tangible or objectively proven, such as meditation to cultivate serenity, mindfulness, insight and impartial judgment, which express an understanding of faith and humble acceptance of the imperfection of the human condition). In addition, it is helpful to teach most people about the processes of thought so that they can be more aware of what biases our perceptions, intentions, and values, and thereby interferes with their functioning.

The Role of Medication in the Treatment of Personality Disorder

Medications are often helpful, but they always carry some risk of side effects, and the advantages and disadvantages must be carefully weighed to respect the patient's wishes and to help them be calm and organized enough for further growth in self-awareness. Medication never makes people more self-aware, which requires learning but can help create more calm and stable conditions for doing psychotherapy. In general, the use of medications should be considered temporary to stabilize the patient and then tapered as awareness and self-regulation improve. The complexity of psychopathology in patients with PD requires the psychiatrist to remain vigilant to idiosyncratic and unpredictable reactions, a high prevalence of side effects, a tendency toward impatience for benefits, and the loss of calm judgment resulting in impulsive decisions or prescribing in desperation.

During the initial stage of treating patients with PDs, medications are often used to target specific symptoms with the goals of relieving subjective distress, risky or self-destructive behaviors, and/or conflict with others, thereby paving the way for later stages of treatment that require calmness, safety, and a reduction in defensiveness, to facilitate growth in self-awareness.

Symptomatic pharmacotherapy is not focused on the individual subtypes of PD but rather on the following four symptom domains shared by all subtypes: (i) mood and anxiety dysregulation, related most strongly to Harm Avoidance, (ii) aggression and impulse control, related most strongly to Novelty Seeking, (iii) social and emotional detachment, related most strongly to Reward Dependence, and (iv) psychotic symptoms and cognitive distortions, related most strongly to intellectual reasoning and Persistence. Recommendations about pharmacotherapy of symptom domains shared by most PDs are summarized in Table 26–24.

Table 26–24.

Commonly Used Medications in Clinical Practice According to Target Symptoms of Personality Disorder

Target Symptom	First-Line Medication	Other Options (Carefully evaluate of risk–benefit ratio and use low doses where appropriate)	Not Recommended
I. Mood dysregulation and anxiety			
Chronic cognitive anxiety[a]	SSRI SNRI GABA Analog (e.g., valproates, pregabalin) Buspirone	MAOI Second Generation Antipsychotic (e.g., quetiapine) Third Generation Antipsychotics (aripiprazole) Clonazepam (short term only)	Benzodiazepine: Generally, not recommended because of the high risk of dependence, abuse and addiction If used, consider a benzodiazepine with a long half-life and use for short trials only: limited to a few days, occasional or intermittent use, or courses not exceeding 2 weeks.
Chronic somatic anxiety	SNRI (e.g., Duloxetine, venlafaxine) GABA Analog Beta-blocker	MAOI TCA	
Obsessions	SSRIs	Second Generation Antipsychotics (e.g., quetiapine) TCA (esp. clomipramine)	

Acute and severe anxiety	Clonazepam, (short term only) Mirtazapine Valproates	Lithium Second Generation Antipsychotics (e.g., quetiapine) Third Generation Antipsychotics (aripiprazole)	
Atypical depression, dysphoria, Classical depression	SSRI SNRI	MAOIs Second Generation Antipsychotics (e.g., quetiapine) Third Generation Antipsychotics (aripiprazole)	TCA: Generally, not recommended as depression may worsen in some patients and due to the risks of overdose.
Emotional lability, rapid cycling	Lithium Lamotrigine Valproates	Second Generation Antipsychotics (e.g., quetiapine) Third Generation Antipsychotics (aripiprazole)	Antidepressants: There is a risk of precipitating mania.

II. Aggression and impulsivity

Affective aggression (Quick temper with normal EEG)	Lithium SSRI Anticonvulsants (e.g., valproates, lamotrigine, carbamazepine)	Second Generation Antipsychotics (e.g., olanzapine, quetiapine)	Benzodiazepine: Generally, not recommended as it frequently induces disinhibition.
Predatory aggression (cold-blooded revenge/cruelty)	No effective pharmacologic treatment.	Second Generation Antipsychotics Lithium	

		Valproates Beta-blocker	
Organic-like aggression (traumatic brain injury)	Beta-blocker Carbamazepine Cholinesterase inhibitor (e.g., donepezil)	Second Generation Antipsychotics (e.g., quetiapine) TCA	
Ictal aggression (abnormal EEG)	Carbamazepine Valproates Diphenylhydantoin Clonazepam		TCA and Antipsychotics: Generally, not recommended as they increase the risk of seizures.
III. Social and emotional detachment			
Chronic asocial disinterest and/or blunted affect	Second Generation Antipsychotics (e.g., quetiapine, clozapine) Third Generation Antipsychotics (aripiprazole)		
IV. Cognitive-perceptual distortions and psychotic symptoms			
Acute and brief psychotic episodes	Second Generation Antipsychotics (e.g., risperidone, quetiapine) Note: Only give for the duration of the symptoms		
Chronic low-level psychosis	Second Generation Antipsychotic (e.g., quetiapine) Third Generation Antipsychotics (aripiprazole)		

---

[a] Psychotherapy is the usual treatment of choice.

(i) Symptom domain of mood dysregulation and anxiety

This symptom domain includes mood instability, typical and atypical depression and/or dysphoria, and chronic cognitive and somatic anxiety.

Emotional instability and mood swings may respond to lithium or valproates (for patients with frequent episodes of euphoria) or lamotrigine (for patients with more frequent depressive episodes). Low-dose atypical psychotropics may be used to stabilize mood or improve depression as the second-line medications. As a general rule, antidepressants may risk an episode of mania in persons with emotional lability or cyclothymia. The risk may be reduced by the combined use of a mood stabilizer. TCAs are extremely dangerous in an overdose, so these drugs ought to be used with caution in patients with PD.

Atypical depression and dysphoria are very frequently observed in patients with any subtype of PD. Serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) are commonly used as first-line treatments. Monoamine oxidase inhibitors (MAOIs) or low-dose atypical psychotropics, such as aripiprazole, ziprasidone, lurasidone, or clozapine, may also be used after careful consideration of the risk–benefit ratio. TCAs are not recommended as at least half of the patients with PD who suffer from atypical depression worsen on TCAs.

Typical depression, including Major Depression, may complicate any PD. These syndromes are treated with antidepressants, including heterocyclics, in doses suggested for primary major depression.

Patients with PD often present with both cognitive anxiety (anticipatory worry) and somatic anxiety (concerns about bodily pains and psychophysiological reactions). While the treatment of choice for chronic cognitive anxiety usually is psychotherapy, especially various forms of CBT, chronic cognitive anxiety may respond to SSRIs, MAOIs, SNRIs, GABA analogs (such as valproates, pregabalin, gabapentin), and (with caution) long half-life benzodiazepines. Chronic somatic anxiety is more responsive to MAOIs, SNRIs (e.g., venlafaxine or duloxetine), and buspirone. Avoidant traits can also be effectively treated with either SSRIs or MAOIs. Some components of somatic anxiety, such as sweating, palpitations, diarrhea, and tremor, can be treated with beta-blockers. Severe, psychotic-like anxiety may respond to low-dose neuroleptics, especially drugs with low D2 affinity (e.g., quetiapine). Despite the relative safety of novel atypical drugs, caution in prolonged use is essential because there is a substantial risk of serious side effects. For example, the use of risperidone carries a risk per person per year of 0.6% for tardive dyskinesia, 0.35% for sudden cardiac death, and 0.02% to 2.44% for neuroleptic malignant syndrome. Therefore, the risk of serious and irreversible side effects is about 1% per person per year and requires careful consideration of the risk–benefit ratio with informed consent.

(ii) Aggression

It is useful, though sometimes difficult, to distinguish different types of aggression. However, diagnosis of different types of aggressive behaviors has important diagnostic implications as well as crucial guidelines for pharmacotherapy. The most common form of aggression occurs when a quick-tempered person is provoked by frustration or threats. Here, the very act of aggression does not have a discernible long-term goal or secondary gain. This is often called "affective aggression" and is frequent in Cluster B impulsive–aggressive individuals who are high in novelty seeking and low in harm avoidance. Aggression that appears to be unprovoked sometimes occurs in patients with cerebral instability documented by an abnormal electroencephalogram (EEG) and is often called "ictal aggression" regardless of any associated personality traits. Predatory aggression or "cruelty" is also known as "organized aggression" because it involves planning, social motives, and/or secondary gains. This type of aggression involves hostile revengefulness and taking pleasure in victimizing others, usually with intact impulse control. Such predatory aggression is most frequent in individuals who are very low in cooperativeness and who are also emotionally dissociated and disengaged, such as Antisocial and Schizoid PD. Finally, "organic-like" aggression is often accompanied by poor social judgment and disinhibition; it is best distinguished from other impulsive–aggressive syndromes by prominent distractibility, inattention, and emotional lability, all characteristic of patients with frontal lobe lesions. These patients also manifest high somatic anxiety with panic and cardiorespiratory symptoms, muscular tension, and motor restlessness.

Multiple double-blind trials have shown the efficacy of lithium carbonate in the treatment of affective aggression. Lithium salts help impulsive–aggressive individuals to be more reflective, that is, to think about consequences before acting on impulse. To a lesser extent, it may be helpful in reducing cruelty and lack of cooperativeness, but this may be an indirect result of reducing impulsivity, which often is a predisposing influence in the development of hostility and revengefulness. Likewise, low-dose atypical neuroleptics may be useful in setting the stage for the patient to modify old habits and assist them in reducing affective aggression. The decision to use long-term neuroleptics requires consideration of potential side effects, such as tardive dyskinesia, and should be made with the carefully informed consent of the patient. Anticonvulsants, such as valproates, lamotrigine, carbamazepine, and oxcarbazepine (to mention only those most frequently used), reduce both the intensity and the frequency of unprovoked angry outbursts in many patients regardless of the normality of their EEG. Double-blind trials have shown that psychostimulants and catecholamine agonists, such as methylphenidate, are often beneficial in the treatment of inattentive and hyperactive adults who are impulsive and aggressive, especially when the symptoms have begun in early childhood.

In accord with postulated serotonergic mechanisms in aggressive behaviors, antidepressants (particularly SSRIs and SNRIs) are considered by many to be beneficial for certain subtypes of impulsive PD (e.g., borderline, histrionic). Finally, MAOIs are effective in some dysphoric states with somatic anxiety and hostility.

There is no effective pharmacotherapy for predatory, premeditated, and cold-blooded aggression. One treatment with some chances of success is psychotherapy, usually CBT. Low-dose traditional neuroleptics (haloperidol) or low-dose novel psychotropics (Risperdal, quetiapine) may help tone down predatory aggression. Of note, antipsychotic-level doses have not been shown more effective here and are not recommended. When accompanied by impulsivity, predatory aggression may improve if treated with beta-blockers.

There are some relative contraindications for the aforementioned listed drugs. Lithium should not be given to antisocial persons without aggression and impulsivity because it does not diminish nonaggressive antisocial behaviors (such as lying, cheating, and stealing) and is poorly tolerated by anxious schizoid individuals. Thus, lithium exposes such patients to the risk of neurologic, renal, and thyroid toxicity without providing much benefit. Likewise, benzodiazepines and alcohol have disinhibiting effects on violence, reduce conditioned avoidance behavior (“loosen inhibitions”), and further impair passive avoidance learning in impulsive antisocial persons. The use of benzodiazepines seems appropriate only in nonaggressive asocial behaviors, for example, patients with schizoid PD. As a general rule, typical and novel psychotropics are used with extreme caution, and the patient is closely monitored so that early signs of complications and adverse effects are recognized and prevented, usually by terminating the offending agent.

(iii) Symptom domain of social and emotional detachment

Emotional detachment, cold and aloof emotions, and disinterest in social relations (“chronic asociality”) are most frequently observed with schizoid and paranoid PD and, to a lesser extent, with antisocial PD. In some cases, emotional detachment or disinterest may respond to novel psychotropics, such as aripiprazole, risperidone, quetiapine, clozapine, olanzapine, or ziprasidone. These medications may help reduce social withdrawal and other features of “aloof” PDs with less risk of extrapyramidal symptoms than with typical neuroleptics. However, dose adjustment is crucial to maintain compliance because of frequent side effects. In cases in which emotional disinterest reflects an underlying depression, antidepressants (SSRIs or MAOIs) frequently help. One should be cautious with TCAs in schizotypal PD because they may worsen and/or trigger psychosis.

(iv) Cognitive-perceptual distortions; psychotic symptoms

Cognitive-perceptual distortions observed in a patient with PD primarily include mild cognitive symptoms, such as bizarre fantasies, eccentric attitudes, suspiciousness, egocentric perception of reality ("everything revolves around me"), nonpsychotic thought disorder (such as ideas of reference and magical thinking), unusual perceptual experiences (such as illusions), and eccentric and bizarre behaviors, among many others. Dissociative phenomena are also frequently observed, such as déjà vu, depersonalization, and derealization. These and similar symptoms can be occasionally observed with all subtypes of PDs but are more frequent in Cluster A and to a lesser extent in Cluster B PDs. These chronic, low-level, psychosis-like but essentially nonpsychotic symptoms may improve indirectly, after pharmacologic stabilization of disturbing affects, and/or after psychotherapeutic correction of underlying cognitive beliefs, and/or after reduction of realistic external stress. For example, a narcissistic person can be "paranoid" that other people have conspired to prevent their success. Psychotherapy is the treatment of choice for this kind of nonpsychotic paranoia. Reflecting the underlying operation of splitting (a primitive defense mechanism that prevents a realistic perception of self and others), the same narcissistic person may at other times perceive these same "enemies" in a diametrically opposite way, as friends or supporters, and even idealize them. In cases in which these symptoms persist and interfere with everyday functioning despite psychotherapy, medications are occasionally needed, usually novel atypical psychotropics (such as aripiprazole, quetiapine).

Table 26–25.
Awakening a Positive Perspective: Four Major Principles of the Science of Well-Being

Positive Approaches to Well-Being	Experiences and Activities	
	Recommended	**Not Recommended**
Letting go of struggles	Acts of hope and self-direction; accepting responsibility Silence of mind, phase 1[a] (calm reflection)	Any violence, fighting, complaining or blaming others consumerism feeding greed/addiction
Working in the service of others	Acts of kindness/cooperation; purposeful giving of oneself Union in nature[a] Silence of mind, phase 2[a] (mindful meditation)	Divisions feeding fear and hate; possessiveness and hoarding; seeking power and dominance
Growing in awareness	Acts of faith and humility; transcendent problem solving Union in nature[a] Listening to the heart[a] Silence of mind, phase 3[a] (contemplation)	Criticism or praise of self and others, depending on external direction, denial of what one does not understand
Understanding thought processes	Calm reflection, mindful meditation, contemplation (silence of mind[a], all three phases)	Seeking justification, depending on external advice, depending on intellect alone

Some chronic cognitive disturbances, such as mild ideas of reference or suspiciousness, tend to subside when the background emotional tension is reduced. For example, alprazolam has been found to be beneficial in patients with borderline personality, particularly those with a history of drug abuse and suspiciousness. However, long-term use of benzodiazepines is associated with a high risk of drug dependence, particularly in patients with PDs, so benzodiazepines like alprazolam should only be prescribed after careful consideration of the risk–benefit ratio and their use carefully monitored for evidence of abuse or dependence.

Chronic cognitive and behavior oddities, such as eccentric attitudes, bizarre behavior, odd beliefs, or extrasensory perceptions, are seen with Schizotypal PD. There is substantial empirical evidence that Schizotypal symptoms ought to be classified among other Schizophrenia Spectrum Disorders. Acute, brief reactive psychoses may complicate most subtypes of PD. These are treated symptomatically, according to accepted pharmacologic practices, most frequently with second-generation atypical psychotropics due to much better safety and tolerability.

Again, acute psychotic symptoms requiring medication may subside when environmental stressors are brought under control; thus, one should be ready to lower the dose or discontinue the medication.

An Integrated Approach to the Treatment of Personality Disorder

Neither medications nor cognitive-behavioral approaches, alone or in combination, are usually adequate to transform a person's personality in a fundamental way. A systematic and integrated approach to personality transformation without tension or conflict has been described by Cloninger as coherence therapy in his book on the Science of Well-Being. The second stage of treating PD involves the awakening of the positive outlooks on life that are needed for well-being, as described in Table 26–25. The basic principles of well-being are summarized in Table 26–25, along with therapeutic experiences and activities for patients that are designed to help them value the dignity of their life and that of others as human beings as a result of self-awareness of each person's body, mind, and psyche. Psychiatry literally means the "healing of the psyche," and the psyche refers to a creative, self-aware consciousness that is more than analytical reasoning. Recovery from mental illness most consistently involves a transformation of a person's spirit or basic perspective about life. However, psychiatrists often become narrowly focused on the reduction of symptoms or risk of harm and forget the importance of helping the patient to maintain self-respect and hope. So often, the insight that psychiatry is the "healing of the psyche" has been neglected or denied as a result of the errors of materialistic and reductionistic thinking. What is meant here by an awakening and healing of the psyche is that the patient becomes directly aware that their worldview (i.e., their outlook on life) has an impact on their thoughts, emotions, and actions. The human outlook on life is what makes people vulnerable to mental disorders, so people must become aware of the assumptions implicit in their initial perspectives. Without some degree of awareness of the consequences of one's initial outlook, it is not possible to transcend the conflicts and contradictions in the thoughts and emotions that derive from these more or less coherent outlooks. As a result, psychotherapies that neglect the stage of spiritual awakening inevitably leave their patients locked in an inner struggle among parts of themselves from which there is no escape, as described poignantly by Freud about himself in ***Civilization and Its Discontents.*** Further information about coaching or therapy to cultivate well-being is available for interested clinicians (http://anthropedia.org).

Once there is an awakening of self-awareness to a metacognitive level, then a patient can proceed to the advanced stages of treatment that are briefly summarized in Table 26–26. Notice now that the patient is behaviorally stable and self-aware, then it is possible to focus on the ***causes*** of the symptoms that were targets of initial intervention during the stabilization phase. For example, the causes of anxiety and dysregulated mood are rooted in a patient's lack of self-respect and trust in others, as expressed in their feelings of separateness, catastrophe, and victimization (see Table 26–26). The therapeutic strategies for addressing each of these sets of causes include psychoeducation, physical and other nonverbal therapies (e.g., psychomotor activities, acupressure), emotional skills training, cognitive skills training, and spiritual exercises. As a result, no one form of therapy (such as behavioral, cognitive, interpersonal, or psychodynamic) is really comprehensive, even with the addition of modules from positive psychology or mindfulness training.

Table 26–26.

Physical, Personal, Social, Cognitive, and Spiritual Therapeutic Procedures for Advanced Character Development (Stages 3 and 4 of Coherence Therapy for Personality Disorders)

Target Problems	Character Goals	Recommended Experiential Activities
1. Mood dysregulation (feeling separate, intolerant/hateful, self-critical, catastrophizing/distressed, victimized)	Trust and self-respect	Psychoeducation about health, sex, stress Physical exercise for relaxation and fitness Reconciliation of anxiety versus risk-taking Recognition of immature automatic thoughts Teamwork to build trust and respect
2. Aggression/impulsivity (being violent, angry, frustrated, greedy/jealous, proud, selfish)	Impulse control and self-mastery	Psychoeducation about nutrition, biorhythms Self-efficacy about cravings/substance abuse Reconciliation of impulsivity versus rigidity Nonviolent assertive communication Social service and acts of forgiveness
3. Social dysregulation (feeling rejected, detached, insecure or cold, unappreciated, unfriendly)	Empathy and secure attachments	Psychoeducation about social signals Empathy training and active listening skills Reconciliation of approval-seeking versus aloofness

		Social problem solving Therapeutic touch and appeasement
4. Cognitive distortion (feeling meaningless, judgmental, dualistic, afraid of death, lacking faith)	Mindfulness and meaning	Psychoeducation about self-transcendence Practice of mindfulness meditation Reconciliation of persistence by virtue Reflection on mysteries of God, life/death Creative works (art, music, writing, etc.)
5. Emptiness (seeking fulfillment, satisfaction, positive emotions, well-being coaching[a], virtue, well-being)	Virtue and well-being	Psychoeducation about well-being Recognizing triggers of negative emotion

Tables 26–24 and 26–26 highlight that the symptomatic targets for psychobiological treatment correspond closely to the skill training modules that have been shown to be moderately effective in the treatment of severe PDs by Marsha Linehan and others, except that the focus is shifted from a behavioral approach to the cognitive perspectives or schemas that lead to the behavioral problems. In addition, a nondualistic approach is taken along a stepwise path of character development to well-being, and emphasis is placed on reconciliation of emotional conflicts that can be measured by the extremes of each of temperament dimensions. In essence, the extremes of each temperament are transcended by the development of particular forms of spiritually elevated thoughts—namely, self-respect reconciles the extremes of Harm Avoidance, self-mastery reconciles the extremes of Novelty Seeking, secure attachments reconcile the extremes of Reward Dependence, and the cultivation of virtues and transcendent meaning reconciles the extremes of Persistence and the limits of the finite human intellect. Both extremes of each temperament have advantages and disadvantages, and transcendence of the underlying conflict resulting from these disadvantages allows a person to live without tension or conflict about these issues as a result of a more holistic initial perspective.

A major practical advantage of therapy modules that focus on the reconciliation of both extremes of each temperament is that heterogeneous groups of patients with widely different personality profiles can be treated together. The focus is on transcending emotional conflicts, coherent character development, and well-being for everyone, not particular personality subtypes. The stigma linked to PD and mental disorders, in general, is mitigated by facing the fact that everyone is imperfect but can learn to live without fear along the path to well-being. The design of therapies has often failed to recognize the path of development of character and well-being and the crucial role of spirituality in transcending and sublimating emotional conflicts. Psychotherapies have almost entirely focused on thought and have generally ignored the body as well as the psyche as a result of the influence of errors in dualistic, behavioral, materialistic, or psychoanalytical thinking. Such an intellectual stance is arrogant and ultimately self-defeating. Alternative therapies have focused on methods that emphasize the body and ignore the benefits of medications or psychodynamics, which is equally arrogant and self-defeating. The coherence therapy described here is based on an integrative psychobiological approach that attends in a balanced way to all three aspects of one’s being—body, mind, and psyche. There is no incompatibility between biologic, psychological, or spiritual aspects of the treatment of PD. In fact, there is a crucial synergy between the components of treatment directed at each aspect because rational brains do not function well when the emotional brain (i.e., limbic system) is distressed. There is much to be learned about the treatment of PD and related mental disorders, but the approach outlined here provides a paradigm that will allow clinicians to integrate what they know about people and bring that to help and guide their treatment of every patient they encounter. It should be emphasized again that advanced psychotherapy or the use of psychotropic medications for the treatment of PD requires expert training or close supervision by an experienced clinician. This is a rapidly advancing area of psychiatry and psychology. Continuing education about the treatment of PD is likely to be especially rewarding for both psychiatrists and their patients because it offers a crucial gateway into the path to well-being and reduced disability from the full range of mental disorders.

Consultation-Liaison Psychiatry and Psychosomatic Medicine

27.1 History and Current Trends

Carol L. Alter, M.D., and Steven A. Epstein, M.D.

Psychosomatic medicine has been a specific area of focus within the field of psychiatry for more than 50 years. The term *psychosomatic* is derived from the Greek words *psyche* (soul) and *soma* (body). The term literally refers to how the mind affects the body. Unfortunately, it has come to be used, at least by the lay public, to describe an individual with medical complaints that have no physical cause and are “all in your head.” In part due to this misconceptualization, the American Psychiatric Association’s (APA’s) *Diagnostic and Statistical Manual of Mental Disorders* (DSM), in 1980, deleted the nosologic term psychophysiological (or psychosomatic) disorders and replaced it with “Psychological Factors Affecting Other Medical Conditions” in DSM-5. Nonetheless, the term continues to be used by researchers and is in the title of major journals in the field (e.g., *Psychosomatic Medicine* and *Journal of Psychosomatic Research*). It is also used by one of the two major national organizations in the field (the American Psychosomatic Society) as well as international organizations (e.g., the European Association of Psychosomatic Medicine). In an effort to better align the name of the field with the practice of the subspecialty, in 2017, the name “consultation-liaison (C-L) psychiatry” was adopted in coordinated efforts resulting in a change in the name of the subspecialty by the American Board of Medical Specialties (ABMS) and the American Board of Psychiatry and Neurology. Similarly, the former Academy of Psychosomatic Medicine became the Academy of Consultation-Liaison Psychiatry, and its journal was renamed the Journal of the Academy of Consultation-Liaison Psychiatry.

ANCIENT HISTORY

According to Hippocrates (460 to 370 BCE), who was influenced by Egyptian and Greek traditions, disease originated within the body and was due to an imbalance in fluid matter. That imbalance could be related to or even caused by a similar imbalance in the patient's external environment. Hippocrates warned the doctor to consider the altitude, the wind direction, the purity of water supply, and the season of the year before making any diagnosis. He pointed out that citizens of cities in particular environments would run to phlegmatic or sanguine temperaments as a reflection of the city's coldness or heat. Physical or fluid imbalance could be caused by emotional upset, too. Hippocrates reported that fear produced sweat and that shame brought on palpitations of the heart; he urged young physicians to look at patients with kindly expressions and never with impatience because impatience could inhibit the return of health. He is said to have cured a king of an intestinal lesion by analyzing a dream. It was Hippocrates who wrote, "in order to cure the human body, it is necessary to have a knowledge of the whole of things."

In *Timaeus*, Plato remarked that trouble in the soul could bring trouble to the body, and, in *Charmides*, Plato quoted Socrates, who had himself attributed the words to a Thracian king: "As it is not proper to cure the eyes without the head, nor the head without the body, so neither is it proper to cure the body without the soul." Aristotle (384 to 322 BC) observed that the emotions of anger, fear, courage, and joy affect the body, and Aretaeus (first century AD) wrote that "the vehement affections of the soul" could cause paralysis.

MODERN HISTORY

As Edward Shorter discusses in detail in his history of psychosomatic illness, ways of presenting illness have varied over history since patients unconsciously manifest symptoms that are thought to represent somatic illnesses. Prior to 1800, physicians did not conduct clinical evaluations and could not distinguish somatic from psychogenic illness. As a result, the diagnoses of hysteria and hypochondriasis could easily be made erroneously in the presence of medical illnesses and did not suggest any specific disease presentations. According to Shorter, “cultural shaping” of patients’ symptoms began in the middle of the 19th century with the popular diagnosis of spinal irritation. That diagnosis was made when a physician believed that spinal cord irritation caused symptoms, and the patient complained of spine sensitivity as well as peripheral symptoms. As was the case for previous explanations of illness, spinal irritation was either an invalid diagnosis in a patient with another medical illness or a “code word” for psychosomatic symptoms. The term “psychosomatic” was first used by Johann Christian Heinroth in 1818.

In the mid-19th century, after much popularity in Europe and the United States, the diagnosis of spinal irritation went out of favor. It was replaced by “reflex neurosis” as an explanation for somatization. That diagnosis was based on the view that any affected organ could cause irritation in any other organ in the body. The conceptualization was based on reflex theory, the notion that nervous connections throughout the body regulate all bodily organs, independent of free will. The Berlin neurologist Moritz Romberg was an influential proponent of the view that the uterus was the cause of hysteria, a reflex neurosis. In this view, hysteria, which encompassed globus hystericus, hysterical seizures, and other psychogenic disorders, was due to irritation of the uterus and the ovaries. He believed that male genitals could also cause hysteria but that they do so less commonly because they are less frequently irritated. In the late 19th century, reflex theory was one of the leading models of nervous illness. Since physicians promulgated the theory to their patients, it is not surprising that they found many of their patients to be preoccupied with their genital organs. Gynecologist August Rheinstadter of Cologne commented skeptically in 1884:

> But now, a true hysteromania, a Furor uterinus, has unfortunately arisen from the previous reluctance of women to undergo a gynecological examination and from the indifference which doctors once displayed towards gynecological disease. So that every woman who suffers from migraine, stomach cramps, or palpitations believes herself to have a uterine illness and indeed will find some physician willing to indulge her in the treatment of this presumed cause.

In the late 19th century, many physicians in Europe and the United States believed that gynecologic problems produced hysteria and other forms of mental illness. As a result, gynecologists performed surgery to treat hysteria and insanity, including the removal of healthy ovaries. The widespread availability of gynecologic surgery in the United States also led women to request such surgery to relieve psychosomatic symptoms. In his history of psychosomatic illness, Shorter notes that some Americans' "addiction to surgery" was due to practitioners convincing the public that vague physical symptoms were due to reflex phenomena from peripheral organs. The nose was the final organ addressed by reflex theory in the late 19th century. One of its chief proponents was Wilhelm Fliess, a Berlin general practitioner, who greatly influenced Freud.

In the 19th century, hysterical fits were the most common form of motor hysteria. There were two primary forms: catalepsy and uncontrolled motor activity such as thrashing about. The psychiatrist Pierre Briquet described over 400 women with hysterical conversion disorders whom he had evaluated at the Pitié-Salpêtrière Hospital in Paris from 1849 to 1859. Many had multiple unexplained somatic complaints; the diagnosis of Briquet syndrome ultimately developed into the diagnosis of somatization disorder which is most similar to the current DSM-5 diagnosis of somatic symptom disorder.

Hysterical paralysis, often due to stressful life events, was apparently quite common through the 19th and early 20th centuries. Louis Verhaeghe, a spa physician in Belgium, wrote in 1850:

> How often do we see patients with paralyzed arms, legs, the side of the face, or even a more limited area such as one or two fingers, problems attributable to an unequal distribution of nervous fluid. It is individuals of a pronounced nervous temperament, subject to hysterical fits, somnambules, persons subject to shameful habits or who abuse the pleasures of love, who are most likely to experience these paralyses.

Astasia-abasia was also seen frequently; Silas Wier Mitchell in Philadelphia referred to it as "hysterical motor ataxia." One of the most prominent physicians of the late 19th century, Jean-Martin Charcot, promulgated a highly influential theory of hysteria. He believed that it was a chronic, inherited functional disease of the nervous system. "In the [hysterical] fit," he said in 1882, "nothing is left to chance, that to the contrary everything unfolds according to the rules, which are always the same and characterize what we see in our outpatients as well as inpatients; they are valid for all countries, for all epochs, for all races, and are, in short, universal.” Although his conception of hysteria was widely disseminated, some physicians who were aware of his ability to suggest symptoms to vulnerable patients were dubious of his theory. The Swiss neurologist Paul Dubois wrote in 1904: “Endowed with the spirit of authority, [Charcot] . . . suggested to them their attitudes and their gestures. Example is contagious even in sickness, and in the great hospitals of Paris, at La Salpêtrière, all cases of hysteria resemble each other. At the command of the chief of the staff, or of the interns, they begin to act like marionettes, or like circus horses accustomed to repeat the same evolutions.” It was not until near the end of his life that Charcot’s theories became more psychologically focused.

Within a decade after he died in 1893, Charcot hysteria had virtually disappeared. Many physicians began to believe that some of his patients most likely had an organic illness. Joseph Babinski’s discovery in 1896 of the Babinski sign was extremely helpful in distinguishing organic disease from hysteria. In 1901, he put forward a new conceptualization of hysteria: It was defined as any symptom that could be induced by suggestion and eliminated by persuasion.

As the reflex model faded in prominence in the late 19th century, the most dominant model became one in which central nervous disease was held responsible for nervous symptoms. In the early 20th century, psychological theories of somatization became popular, but they became dominant only in the latter half of the 20th century. “Neurasthenia,” or tired nerves, was a new diagnosis at the end of the 19th century that was brought to prominence by George Beard, a New York neurologist. A term applied broadly, the diagnosis encompassed depression, anxiety, somatization, male hysteria, and chronic fatigue. Wilhelm Stekel, a Viennese psychoanalyst, coined the term “somatization” in the 1920s.

Sigmund Freud was the principal theoretician to bring psyche and soma back together. He demonstrated the importance of emotions in producing mental disturbances and somatic disorders. His early psychoanalytic formulations detailed the role of psychic determinism in somatic conversion reactions. Picking up where the Greeks and Romans had left off, Freud redignified the study of the emotions as a separate study and pointed to their relationship with the soma in the new field of psychiatry. Using Freud’s insight, a number of workers in the early decades of the 20th century tried to expand the understanding of the interrelationship of psyche and soma. The influence on adult organ tissue of various unresolved pregenital impulses was proposed by Karl Abraham in 1927, the application of the idea of conversion reaction to organs under the control of the autonomic nervous systems was described by Sandor Ferenczi in 1926, and the attaching of symbolic meaning to fever and hemorrhage was suggested by George Groddeck in 1929.

In the 20th century, somatization symptoms changed from predominantly neurologic (e.g., hysterical paralysis) to other symptoms such as fatigue and chronic pain. Edward Shorter attributes this change to three causes: (1) improvements in medical diagnostic techniques made it easier to rule out organic causes for neurologic disease; (2) the central nervous system (CNS) paradigm faded; and (3) social roles changed (e.g., the disappearance of the historical notion that “weak” women would be expected to have fainting spells and paralysis).

Although hysterical neurologic symptoms have remained relatively less common in the 21st century, CNS explanations of chronic pain and fatigue are gaining prominence. For example, functional brain research has demonstrated brain dysfunction and possibly genetic contributions among some individuals with fibromyalgia and chronic fatigue syndrome. Those syndromes, while still thought by some to represent somatization variants, are currently established medical diagnoses.

HISTORY OF PSYCHOSOMATIC MEDICINE RESEARCH

Since the mid-20th century, research in psychosomatic medicine and C-L psychiatry has taken two interconnected paths. Psychosomatic medicine research has generally focused on understanding psychophysiological mechanisms underlying mind–body relationships. C-L research, however, has largely been directed at understanding psychiatric problems among clinical populations with medical illnesses.

In the early 20th century, two theoretical trends developed, one suggesting that specific emotions led to specific cell and tissue damage, and the second that generalized anxiety created the preconditions for a number of not-necessarily predetermined diseases. Cases of shell shock during World War I and new endocrine studies provided observations for the swell of interest in theory evidenced in the 1930s.

In the early 1930s, Franz Alexander, who had left Berlin to move to Chicago, where he founded the Chicago Institute for Psychoanalysis, described how he believed specific psychological conflicts caused specific somatoform symptoms. Alexander saw conflict as a stress and suggested that, when conflict presents itself, the individual may suppress the stress and produce, through the voluntary nervous system, a reaction such as the conversion reaction described by Freud. Alternatively, after suppressing stress, the individual's sympathetic responses may remain alert for heightened aggression or flight, or parasympathetic responses may remain alert for heightened vegetative activity. According to these theories, prolonged alertness and tension can produce physiologic disorders and eventual pathology of visceral organs.

For instance, Alexander postulated that in a passive-dependent person without someone to satisfy their dependence, stress is created. That particular stress may stimulate and keep alert the parasympathetic nervous system, which means that too much gastric acid is secreted, and gastric hypermotility results, all of which may lead to a peptic ulcer. Another dependent person with a different genetic profile may, in repressing conflict, stimulate parasympathetic overfunctioning through pathways leading to colitis or asthma. Still, other dependent persons' efforts to move beyond dependency result in overstimulation of the sympathetic system, and the resulting chronic alertness produces migraine, hypertension, or arthritis.

Although there were multiple case reports supporting Alexander's views, it has not been demonstrated that the same specific conflicts are present in all cases of the same disease. Early methodologically flawed reports were rooted in psychoanalytic explanations of "psychosomatic" illnesses. This work had numerous problems, including selection bias, small sample size, and lack of control groups.

A number of investigators developed the pathway concept into other theories involving the whole personality. In 1954, Flanders Dunbar proposed that the ambitious, hard-driving person would be prone to coronary occlusion. That personality type is similar to the competitive, restless, time-haunted, and coronary-bound type A person proposed by M. Friedman and R. H. Rosenman in 1959.

A second trend in psychosomatic medicine that began in the middle of the 20th century has been to investigate what happens to a person in a nonspecific way when faced with stress. In the 1950s, Harold Wolff and Stewart Wolf observed that chronic hyperfunction or chronic hypofunction in the vascular and secretory activities of the mucosa of the gastrointestinal (GI) and respiratory systems could produce pathology. Overfunctioning of the mucosa was correlated with hostility, and underfunctioning was correlated with fear or sadness. The patient's entire reactive patterning and their life history account for whether they react to stress by hyperfunctioning or hypofunctioning.

Other workers in the nonspecific group described various possible mechanisms by which psychologically induced stress may cause organic disease in humans and animals. In 1950, Hans Selye thought that the hypophyseal–adrenocortical axis responded to various types of physical and psychic stress with hormonal changes that can ultimately cause a variety of organic diseases, such as rheumatoid arthritis and peptic ulcer disease. Selye viewed such diseases as a byproduct of the body's attempt to adapt to stress from any source.

Experimental psychologists with a learning theory conception of behavior studied the effects of chronic unrelieved anxiety in humans and animals and found that gastric hydrochloric acid production increases under such circumstances. Because such acidity is a precursor of peptic ulcer, they concluded that chronic anxiety is the variable intervening between the behavioral and physical events involved in psychosomatic illness. Modern research provides some support for the role of stress as a predisposing factor for the development of peptic ulcer disease (e.g., the work of Levenstein).

Beginning in the late 1960s, T. H. Holmes and R. H. Rahe showed that life crises often precede illness and that there is some correlation between the intensity of the crisis and the severity of the illness that follows; the crisis ranked as the most intense by subjects was the death of a spouse. George Engel suggested a giving-up–given-up complex, in which individuals feel powerless to change their environments or themselves and eventually lose the will to try, becoming mentally or physically ill, perhaps because of changes in the immunologic and neuroendocrine systems.

As exemplified by the long history of psychosomatic research in pain and GI disease, the quality of research in the field has evolved significantly over the past 70 years. Early research efforts were psychoanalytically oriented case studies of conditions such as ulcerative colitis. Such research often led to invalid conclusions. For example, one report by A. Johnson and colleagues in 1947 of a series of 33 patients with rheumatoid arthritis led to the preliminary conclusion that women with this disorder have “a chronic inhibited hostile aggressive state as a reaction to the earliest masochistic dependence on the mother that is carried over to the father and all human relationships, including the sexual.” Nonetheless, even those authors were aware of potential methodologic limitations of their work: “but these factors . . . are found so commonly in patients who do not suffer from arthritis that additional etiologic factors, still unknown, must be postulated.”

Psychophysiological research began in the first half of the 20th century. Researchers used techniques such as electromyogram (EMG), electroencephalogram (EEG), and galvanic skin response to examine physiologic parameters among individuals with a variety of psychosomatic illnesses. Research has evolved to the present day to include areas such as heart rate variability and stress and the role of the CNS in illnesses such as functional movement disorders, fibromyalgia, and chronic fatigue syndrome. Pain treatment research has evolved from less-controlled studies to randomized-controlled studies.

As early as the 1960s, researchers reported on the prevalence of various psychiatric problems in inpatient and outpatient medical settings. Methodologic variability led to wide variation in estimates of comorbidity. Early work also reported on the characteristics of patients referred for psychiatric consultation. R. J. Kahana’s and G. L. Bibring’s classic work in 1964 emphasized the importance of understanding personality types to the effective treatment of one’s patients.

C-L psychiatry research in the mid-20th century also elucidated the most common reasons for psychiatric consultation. While many of those reasons hold true to this day, psychoanalytic influences on physician consulting behavior have clearly waned in recent years. Consider Zbigniew Lipowski’s summary in 1967 of the two most common diagnostic questions asked of the consulting psychiatrist:

Table 27.1–1.
Typical Reasons for a Psychiatric Consultation (After Z. Lipowski)

1. Suicidal attempt or threat
2. Grossly disturbed behavior, e.g., delirium and psychosis
3. Excessive emotional reactions, e.g., depression and anger
4. Refusal to cooperate
5. Delayed convalescence
6. Conflict between patient and personnel
7. Patient with a psychiatric history
8. Psychiatric side effects of drugs
9. Selection and/or preparation of patients, e.g., for surgery
10. Disposition

1. Is this particular bodily complaint (or set of complaints) explicable as an expression of psychological ill-health, that is, is it partly or wholly psychogenic?
2. Is the inner experience of psychic change reported by the patient or his observable behavior explicable as the direct results of, or a psychological reaction to, organic disease?

However, reasons for requests for assistance in patient management have seemingly changed very little since Lipowski summarized them in 1967 (Table 27.1–1) and will be familiar to all currently practicing consultation-liaison psychiatrists.

Table 27.1–2 outlines the history of psychosomatic medicine.

CURRENT TRENDS

The practice of C-L psychiatry has evolved considerably since its early clinical origins and has come to focus on psychiatric illnesses that occur in the setting of physical health care. In large part, this evolution has occurred as a result of the increased complexity of medicine, the increased understanding of the relationship of medical illness to psychiatric illness, and the greater appreciation of mind and body as one. A key outcome of this has been the granting of subspecialty status for C-L psychiatry. Clinical care is now delivered in a variety of health care settings and utilizes an ever-expanding set of diagnostic tools as well as many effective somatic and psychotherapeutic interventions. Research in the area has progressed to include a greater understanding of the relationship between chronic medical conditions and psychiatric disorders and has examined the pathophysiologic relationships, the epidemiology of comorbid medical, and psychiatric disorders, and the role that specific interventions play in physiologic, clinical, and economic outcomes.

Table 27.1–2.

Major Conceptual Trends in the History of Psychosomatic Medicine

I. Psychoanalytic

Sigmund Freud (1900): Somatic involvement occurs in conversion hysteria, which is psychogenic in origin—e.g., paralysis of an extremity. Conversion hysteria always has a primary psychic cause and meaning; i.e., it represents the symbolic substitutive expression of an unconscious conflict. It involves organs innervated only by the voluntary neuromuscular or the sensorimotor nervous system. Psychic energy that is dammed up is discharged through physiologic outlets.

Sandor Ferenczi (1910): The concept of conversion hysteria is applied to organs innervated by the autonomic nervous system; e.g., the bleeding of ulcerative colitis may be described as representing a specific psychic fantasy.

George Groddeck (1910): Clearly organic diseases, such as fever and hemorrhage, are held to have primary psychic meanings; i.e., they are interpreted as conversion symptoms that represent the expression of unconscious fantasies.

Franz Alexander (1934, 1968): Psychosomatic symptoms occur only in organs innervated by the autonomic nervous system and have no specific psychic meaning (in contrast to conversion hysteria) but are end results of physiologic accompaniments of certain specific unconscious repressed conflicts. Presented first conceptualization of the biopsychosocial model.

Helen Flanders Dunbar (1936): Specific personality types are associated with specific psychosomatic diseases, an idea similar to Meyer Friedman’s 1959 theory of the type A coronary type.

Peter Sifneos, John C. Nemiah (1970): Elaborated the concept of alexithymia. Developmental arrests in the capacity to identify and express conflict-related affect result in psychosomatic symptom formation.

II. Psychophysiologic

Walter Cannon (1927): Demonstrated the physiologic concomitants of some emotions and the important role of the autonomic nervous system in producing those reactions. The concept is based on Pavlovian behavioral experimental designs.

Harold Wolff (1943): Attempted to correlate life stress to physiologic response, using objective laboratory tests. Physiologic change, if prolonged, may lead to structural change. He established the basic research paradigm for the fields of psychoimmunology, psychocardiology, and psychoneuroendocrinology.

Hans Selye (1945): Under stress a general adaptation syndrome develops. Adrenal cortical hormones are responsible for the physiologic reaction.

Meyer Friedman (1959): Theory of type A personality as a risk factor for cardiovascular disease.

Robert Ader (2007): Beginning in the 1970s, established the basic concepts and the research methods for the field of psychoneuroimmunology.

III. Sociocultural

Karen Horney (1939), James Halliday (1948): Emphasized the influence of culture in the development of psychosomatic illness. They thought that culture influences the mother, who, in turn, affects the child through her relationship with the child—e.g., nursing, child-rearing, and anxiety transmission.

Thomas Holmes, Richard Rahe (1975): Correlated the severity and the number of recent stressful life events with the likelihood of disease.

IV. Systems theory

Adolph Meyer (1958): Formulated the psychobiologic approach to patient assessment that emphasizes the integrated assessment of developmental, psychological, social, environmental, and biologic aspects of the patient’s condition. Basic concept of the biopsychosocial model is implicit in his approach.

Zbigniew Lipowski (1970): A total approach to psychosomatic disease is necessary. External (ecologic, infectious, cultural, environmental), internal (emotional), genetic, somatic, and constitutional factors, as well as past and present history, are important and should be studied by investigators working in the various fields in which they are trained.

George Engel (1977): Coined the term “biopsychosocial” derived from general systems theory and based on conceptual ideas introduced much earlier by Alexander and Meyer.

Leon Eisenberg (1995): Contemporary psychiatric research demonstrates that the mind–brain responds to biologic and social

> vectors while being jointly constructed of both. Major brain pathways are specified in the genome; detailed connections are fashioned by, and consequently reflect, socially mediated experience in the world.

Psychiatric morbidity is very common in patients with medical conditions, with a prevalence ranging from approximately 20% to 65%, depending on the illness. Patients in the general hospital have the highest rate of psychiatric disorders when compared to community samples or patients in ambulatory primary care. For example, compared to community samples, depressive disorders in the general hospital are more than twice as common, and substance abuse is two to three times as common. Delirium occurs in approximately 20% of inpatients. Psychiatric morbidity has serious effects on medically ill patients and is often a risk factor for exacerbation of their medical conditions. It is well established that depression is both a risk factor and a poor prognostic indicator in coronary artery disease. Psychiatric illness worsens cardiac morbidity and mortality in patients with a history of myocardial infarction, diminishes glycemic control in patients with diabetes, and decreases return to functioning in patients experiencing a stroke. Depressive and anxiety disorders compound the disability associated with stroke. In the context of neurodegenerative diseases such as Parkinson disease or Alzheimer disease, depression, psychosis, and behavioral disturbances are significant predictors of functional decline, institutionalization, and caregiver burden. Hospitalized patients with delirium are significantly less likely to improve in function compared to patients without delirium. Delirium is associated with worse outcomes after surgery, even after controlling for the severity of medical illness.

In addition, depression and other mental disorders significantly impact the quality of life and the ability of patients to adhere to treatment regimens (e.g., in patients with diabetes mellitus). Psychiatric disorders are linked to nonadherence with antiretroviral therapy, adversely affecting the survival of human immunodeficiency virus (HIV)-infected patients, and they worsen the prognosis and quality of life of cancer patients. Patients with mental disorders also have a much higher chance of being homeless, living in poverty, or experiencing other adverse social determinants of health, such as financial and nutritional insecurity. All of these factors substantially increase health risks and outcomes.

Failure to identify, evaluate, diagnose, treat, or achieve symptom resolution of psychiatric morbidity in medical care settings results in significantly increased service utilization. For example, depression, dementia, and delirium are associated with higher utilization of medical care, both in the hospital (longer lengths of stay) and after discharge. Untreated depression is associated with higher medical utilization after hospital discharge and with higher mortality and morbidity in coronary disease, hypertension, diabetes, and stroke.

THE CLINICAL PRACTICE OF CONSULTATION-LIAISON PSYCHIATRY

The primary focus of C-L psychiatry is the diagnosis and treatment of psychiatric disorders in patients with complex medical conditions. Thus, C-L psychiatry addresses a variety of clinical problems that occur in patients being treated in medical settings, including psychiatric disorders such as delirium and dementia, which occur as a *result* of a medical condition; anxiety or depression, which occur *in the setting* of chronic medical conditions but may also be due to medical causes; and somatic symptom disorders. In addition to the care of specific conditions, C-L psychiatry encompasses a variety of other clinical activities that occur in the medical setting, including evaluation of decision-making capacity, attention to quality of life and symptom management in chronic and terminally ill individuals, provision of liaison services to medical staff, and assistance with management of primary psychiatric conditions such as bipolar disorder or schizophrenia. Table 27.1–3 summarizes the types of clinical problems addressed in C-L Psychiatry.

Table 27.1–3.
Summary of Clinical Problems in C-L Psychiatry

Type of Clinical Problem	Example
Psychiatric symptoms secondary to a medical condition	Delirium, dementia
Psychiatric symptoms as a reaction to medical condition or treatments	Anxiety related to chemotherapy; depression related to limb amputation
Psychiatric complications of medical conditions and treatments	Mania secondary to corticosteroid treatment
Psychological factors contributing to medical symptoms	Somatic symptom disorders
Medical complications of psychiatric conditions or treatment	Neuroleptic malignant syndrome; acute withdrawal from alcohol or other substance
Co-occurring medical and psychiatric conditions	Recurrence of depressive disorder in the setting of cancer treatment (conditions occur independently); schizophrenia in a patient with end-stage renal disease.
Psychiatric/psychosocial assessment	Decision-making capacity evaluation; evaluation prior to organ transplantation

C-L psychiatry is practiced in a variety of settings and encompasses a combination of consultative, treatment, and liaison activities. Historically, the majority of this work occurred within the general hospital setting. Largely this has been due to the fact that the greatest risk factor for requiring psychiatric intervention has been the severity of the medical illness. However, as more illnesses become chronic in nature (e.g., cancer and HIV), there has been an increase in the delivery of C-L services in outpatient settings as well. Regardless of where care is delivered, the basic approaches are similar: To conduct a psychiatric assessment, provide psychotherapeutic, behavioral, or pharmacologic interventions to patients, and work closely with other medical professionals in a liaison capacity.

EVALUATION PROCESS IN CONSULTATION-LIAISON PSYCHIATRY

Evaluation in the medical setting includes a standard psychiatric assessment as well as a particular focus on the medical history and context of physical health care. In addition to obtaining a complete psychiatric history, including a past history, family history, developmental history, and a review of systems, the medical history, and current treatments should be reviewed and documented. A full mental status examination should be completed, and focused neurologic and physical examinations are often indicated depending on the nature of the presenting problem.

Several components of the process should be emphasized. First, it is critical to communicate with the referring clinician. In many cases, the reason for consultation is not clear, and it is often helpful to understand why the treating team believes the patient might have a psychiatric problem. Such information can guide the assessment and may provide information about other concerns the treatment team might have, including the patient's behavior and over or underuse of treatment, such as pain medication. It may also reveal the team's frustration with a particular patient. Second, collateral information from family members and other health care providers, including mental health professionals, is important in understanding any prior history of psychiatric problems and helping the team plan for ongoing care. Third, while the interview of the patient should be comprehensive, it also needs to be sensitive to the patient's medical status. In many cases, patients in the general medical setting are experiencing pain or discomfort, distracted by medical problems, or cognitively compromised. Thus, the interview may need to be focused on the reason for consultation.

A full mental status examination, including a specific focus on cognitive functioning, should be completed. The mental status should address the level of consciousness, attention, concentration, memory, executive function, language, praxis, mood, affect, perception, judgment, and insight. The Mini-Mental State Examination or Montreal Cognitive Assessment is often a helpful component because it provides an objective score that can serve as a baseline for retesting, especially when delirium or dementia is a concern.

The psychiatric consultant should also ensure that appropriate laboratory and other diagnostic evaluations have been conducted. Basic chemistry, hematologic, and cardiovascular workup can be supplemented with other tests, including thyroid function, liver function, vitamin B_{12}, folate, toxicology, serologic tests for syphilis, and HIV testing. Additional diagnostic studies, including computed tomography (CT) or magnetic resonance imaging (MRI), scans of the brain, EEG, or lumbar puncture, may also be indicated.

Another important objective of the psychiatric evaluation is to gain an understanding of the patient's experience of their illness. In many cases, this becomes the central focus for both the psychiatric assessment and interventions. It is often helpful to develop an understanding of the patient's developmental and personal history as well as key dynamic conflicts, which in turn may help to make the patient's experience with illness more comprehensible. Such an evaluation can include the use of the concepts of stress, personality traits, coping strategies, and defense mechanisms. Observations and hypotheses that are developed can help to guide psychotherapy with patients aimed at diminishing distress and may also be helpful for the primary medical team in their interactions with the patient.

Finally, a full report synthesizing the information should be completed and should include specific recommendations for additional evaluations and intervention. The psychiatrist should limit information in the report to that which is medically necessary. Ideally, the report should be accompanied by a discussion with the referring physician.

TREATMENTS USED IN CONSULTATION-LIAISON PSYCHIATRY

A host of interventions have been successfully utilized in C-L psychiatry. Specific consideration must be given to medical illness and treatments when making recommendations for psychotropic medications. Psychotherapy also plays an important role and may vary in its structure and outcomes as compared to therapy that occurs in mental health practice.

Psychopharmacologic recommendations need to consider several important factors. In addition to targeting a patient's active symptoms, considering the history of illness and treatments, and weighing the particular side effect profile of a particular medication, there are several other factors that must be considered that relate to the patient's medical illness and treatment. It is critical to evaluate potential drug–drug interactions and contraindications to the use of potential psychotropic agents. Since the majority of psychotropic medications are metabolized in the liver, awareness of liver function is important. General appreciation of side effects, such as weight gain, risk of development of diabetes, and cardiovascular risk, must be considered in the choice of medications. In addition, it is also important to incorporate knowledge of recent data that outline the effectiveness and specific risks involved for patients with co-occurring psychiatric and physical disorders. For example, a greater understanding of the side effects of antipsychotic medications has raised concerns about the use of these medications in patients with dementia.

Psychosocial interventions also require adaptation when used in this population. The methods used and the goals of psychosocial interventions in the medically ill are often determined by the consideration of disease onset, etiology, course, prognosis, treatment, and understanding of the nature of the presenting psychiatric symptoms, in addition to an understanding of the patient's existing coping skills and social support networks.

Every major psychosocial intervention has been used in C-L psychiatry, including dynamic, supportive, and cognitive behavioral interventions, delivered in family, group, and individual settings. The goals for psychosocial interventions vary widely depending on the nature of both the psychiatric issues and the medical illness. In addition, the specific intervention will vary based on the illnesses and goals. For instance, while a goal generally present for all medical illnesses may be addressing changes in role and function resulting from illness, addressing concerns regarding death and dying will be a key concern for those in the terminal phases of an illness such as cancer. Coping with changes in physical function and pain are key issues that can be addressed for patients with arthritis. Addressing barriers to adherence to treatment becomes critical to psychosocial interventions in patients with diabetes.

An extensive body of research has demonstrated positive clinical outcomes associated with a variety of interventions. At a minimum, psychosocial interventions have been shown to improve quality of life and psychiatric conditions; in addition, there is some evidence that psychosocial interventions may positively impact treatment adherence and medical outcomes. Interventions aimed at depression in patients with diabetes have shown not only decreases in depressive symptoms but also reduction in medical costs of care.

MENTAL DISORDERS IN PRIMARY CARE

An area of considerable focus has been the successful identification and management of patients with mental disorders treated in the primary care setting. Mental health conditions are highly prevalent, ranging from 30% to 60% depending on the chronic health condition being treated, but are often not recognized and not effectively treated in most cases. In addition, patients with mental health conditions and other chronic health conditions are two to three times more expensive than those without psychiatric comorbidities. Although a variety of interventions, including education of primary care physicians (PCPs), screening initiatives, and implementation of quality improvement programs, may have a short-term benefit, they have not demonstrated a long-term impact on the detection and treatment of mental health and substance use conditions.

Programs that incorporate access to mental health services within primary care have resulted in improved detection and treatment of these common conditions. Colocation programs, often described as primary care behavioral health (PCBH), increase interaction between mental health providers and PCPs and may be more convenient for patients receiving care in primary care settings. PCBH has been shown to improve outcomes for those patients participating in the programs but is limited in its ability to improve screening, diagnosis, or treatment outcomes over larger populations.

The Collaborative Care Model (CoCM) provides a systematic approach to the care of mental health conditions in the primary care setting. In this approach, a behavioral health care manager and a psychiatrist (who serves as a consultant) work with the PCP to screen, diagnose, and treat patients with mental health conditions. Randomized-controlled trials of CoCMs for treating depression and other common mental health and substance use conditions in primary care settings have shown that they significantly improve the quality of care and outcomes for mental health disorders (such as depression and anxiety), improve patient and provider satisfaction, and increase patient adherence to the treatment regimen. Evidence supports its use for most mental health and substance use conditions. Reimbursement for the service began in 2017, and since that time, there has been increasing availability of the model.

RESEARCH IN PSYCHOSOMATIC MEDICINE

Research in psychosomatic medicine has focused on several key areas that have contributed to the current understanding of the burdens of co-occurring psychiatric and medical disorders. Important advances in psychosomatic medicine research have identified common pathways between psychiatric illness and physical illnesses, such as cardiovascular disease or diabetes, a bidirectional risk associated with the presence of psychiatric disorders or medical conditions such as stroke, and the identification of clinical interventions that can impact both medical and psychiatric outcomes. However, research in psychosomatic medicine has been limited by the complexity of research questions that require investigation of both medical and psychiatric outcomes and the existing “division” of the research enterprise into separate psychiatric and medical domains.

Table 27.1–4.

Current Research in Psychosomatic Medicine

Types of Studies	Examples of Current Research
Epidemiologic Studies	
Occurrence, nosology, and impact of different types of psychiatric morbidity over the course of general medical conditions	PTSD and other psychiatric comorbidities in individuals with traumatic brain injury
Mechanistic Studies	
Understanding the role of psychosocial, biologic, and genetic factors in the causation of psychiatric and medical morbidity	Affective circuitry in chronic pain Social support and biologic changes such as inflammation Social determinants of health
Examining the social, psychological, biologic, and genetic factors involved in somatic symptom disorders, chronic pain, and fatigue	Depression and chronic pain Functional brain imaging abnormalities in chronic fatigue and conversion
The effects of medical illnesses and their treatments on the brain and on the development of secondary psychiatric disorders	Medications that may cause delirium Paraneoplastic limbic encephalitis
Understanding how psychiatric morbidity affects medical outcomes	Depression and adherence to medical treatments
Treatment Studies	
Efficacy and safety of psychiatric treatments as applied to the complex medically ill	Cognitive behavioral therapy in somatic symptom disorders The efficacy and safety of α-2 adrenoreceptor agonists in treating delirium
How treating psychiatric conditions may affect physical	The effect of treating depression on hemoglobin A_{1c} levels in diabetic

health outcomes	patients. The impact of brief psychotherapy interventions on immune response across different disease states. The effect of mindfulness therapies on a patient with degenerative neurologic diseases.
Service Delivery Studies	
The delivery of efficacious psychiatric treatments for the complex medically ill across different service settings, such as primary care, home-based care, and long-term care settings	Use of collaborative care strategies in primary and specialty care settings
Development of population health models that incorporate risk for psychiatric disease into the overall management of health and economic outcomes	Use of risk modeling to identify patients who can benefit from psychiatric consultation in inpatient settings. Use of implementation science to maximize the use of population-based strategies

Various conceptual models of the relationship between medical and physical illness underlie the core research areas. For example, a large body of epidemiologic work has examined the relationship of depressive disorders to poor outcomes among patients with cardiovascular disease. In contrast, in the field of psychoneuroimmunology, basic science techniques are used to examine the relationship between psychosocial stressors and immune functioning. Table 27.1–4 presents an overview of conceptual areas and specific current research areas.

CURRENT PSYCHOSOMATIC MEDICINE RESEARCH

Psychosomatic medicine is now involved with a wide, ever-expanding spectrum of investigations examining the medical illness–psychiatry relationship. Important contributions have occurred in acquired immunodeficiency syndrome (AIDS), cancer, transplantation, cardiac, neurologic, pulmonary, renal, GI disease, and obstetrics and gynecology. In each of these areas, first-generation studies identified the extent and nature of psychiatric morbidity associated with the most common diseases. More sophisticated second-generation cross-sectional epidemiologic studies have established the prevalence rates of a broader range of psychiatric disorders in several medical conditions, as well as newer psychiatric syndromes, such as mild traumatic brain injury.

In some cases, a new body of research has extended the knowledge about genetic, neurochemical, and behavioral factors contributing to the development of psychiatric disorders among complex medically ill populations. This work has shown that many different mechanisms are involved. Examples include the relationships between depression and diabetes and between specific autoantibodies and limbic encephalitis. This research has led to some intervention studies focused on reducing the rate of occurrence of these disorders, for example, hospital programs that reduce the incidence of delirium.

Of long-standing interest to psychosomatic medicine has been the relationship between emotional factors and disease development. Recent studies have demonstrated the dramatic impact of coexisting psychiatric morbidity on the course or outcome of specific medical illnesses. Studies have also been extended to examine the effect of psychiatric comorbidity on health costs. Comorbid psychiatric disorders have been shown to increase the length of hospital stay and rehospitalization rates in numerous illnesses. Several cost-effectiveness studies have demonstrated the value of C-L psychiatry interventions in hospital and outpatient populations. In addition, psychobiologic research continues to focus on emotional factors and illness development in individuals who do not necessarily have psychiatric illnesses. For example, there continues to be important work in the relationship between emotional stressors and the functioning of the immune system.

THE FIELD OF PSYCHOSOMATIC MEDICINE AND C-L PSYCHIATRY

The term “Psychosomatic Medicine” was first used by Felix Deutsch in the early 1920s. Organized psychosomatic medicine and C-L psychiatry had their origins in the publication of the journal *Psychosomatic Medicine* in 1939, the founding of the American Psychosomatic Society in 1947, and the journal *Psychosomatics* in 1960. In 1968, John Schwab published the first C-L psychiatry textbook. The Academy of Psychosomatic Medicine was founded in 1953 and has been the national organization for C-L psychiatrists. In 2017, the organization adopted the new name Academy of Consultation-Liaison Psychiatry.

The origins of C-L psychiatry fellowships can be traced to George Engel's and John Romano's fellowship program in psychosocial skills at Rochester University College of Medicine. This program, first offered in 1946, was offered to nonpsychiatric physicians as well as psychiatrists. The Massachusetts General Hospital established its first consultation service in 1954.

In 2003, the ABMS approved psychosomatic medicine as a subspecialty field of psychiatry. The approval of the subspecialty was both a response to and an opportunity for the field to highlight and expand the foundation in clinical care, research, teaching, and other scholarly activities related to the care of this special patient population. Although C-L specialists do not provide all, or even most, of the care to this patient population, the presence of the subspecialty clearly has had a positive impact on general training, research, and academic psychiatry. In 2017, the ABMS approved a name change of the field to C-L psychiatry.

C-L psychiatry, as defined and characterized by the subspecialty, is practiced by psychiatrists. The Academy of Consultation-Liaison Psychiatry has approximately 2,000 members, and about 3,000 psychiatrist members of the APA state that they are interested in or spend a substantial amount of time providing consultation in a general hospital setting. Other mental health professionals also provide care for this population. Psychologists have long served in the general medical setting providing assessments, psychotherapeutic, and behavioral interventions, and conducting research. The health psychology section of the American Psychological Association has approximately 3,000 members. In addition, social workers and nurses participate in care for these patients, including in collaborative care programs. In many settings, C-L psychiatrists function as part of multidisciplinary teams, which include psychiatry, psychology, nursing, and social work. In most cases, these teams work within medical specialty settings that provide care to special populations such as those with HIV, cancer, cardiovascular disease, transplant, and diabetes.

The APA formed the Council on Psychosomatic Medicine (now Council on Consultation-Liaison Psychiatry) in 2004 in response to the approval of the subspecialty. The APA Council and the Academy of Consultation-Liaison Psychiatry, as well as other organizations, have participated actively in the development of clinical standards, addressed issues related to access to care and reimbursement, and provided education to members, trainees, medical professionals, and the public. Care of special populations such as those with cancer, HIV, transplant, and obstetrics and gynecology is the focus of other organizations (e.g., American Psychosocial Oncology Society and North American Society for Psychosocial Obstetrics and Gynecology). Research is a core interest for some organizations, including the American Psychosomatic Society. In addition to the organizations in the United States, there has been continued strong interest in the field internationally (e.g., The European Association of Psychosomatic Medicine).

Education and training in C-L psychiatry are integrated throughout the psychiatry curriculum in medical school and general psychiatric training. Starting in 1961, the Accreditation Council for Graduate Medical Education (ACGME) addressed the need for psychiatric residents to collaborate with other services besides psychiatry, including medicine, pediatrics, and neurology. By the 1980s, the ACGME's Residency Review Committee (RRC) required all psychiatry residency programs to provide teaching and experience in the specialty. The current RRC requirements require at least 2 months of full-time work in which residents consult under supervision on other medical and surgical services.

Currently, there are 62 ACGME-accredited C-L fellowship programs in the United States. The ACGME program requirements for C-L psychiatry fellowships can be found on their website (www.acgme.org). Table 27.1–5 lists the clinical activities in which C-L psychiatry fellows must demonstrate competence. In addition, there are over 30 residencies that combine psychiatry with internal medicine, family practice, pediatrics, or neurology.

Table 27.1–5.
Patient Care Competencies Required of All Consultation-Liaison Psychiatry Fellows

1. Establishing rapport with all medical patients.
2. Diagnosing and treating psychiatric disturbances that occur among the physically ill.
3. Conducting psychiatric evaluations of individuals who have psychiatric complications of medical illnesses; psychiatric complications of medical treatments, including medications, traditional and new surgical or medical procedures, transplantation, and experimental therapies; and typical and atypical presentations of psychiatric disorders due to medical, neurologic, and surgical illnesses.
4. Evaluating and managing individuals with acute and chronic pain; delirium, dementia, and psychiatric disorders due to medical illness; somatic symptom disorders; palliative care and end-of-life issues; and issues in adjusting to the emotional stresses of medical illness.
5. Assessing the capacity of individuals to give informed consent for medical and surgical procedures in the presence of cognitive impairment.
6. Providing psychosocial interventions, including psychotherapeutic interventions appropriate for the medically ill.
7. The appropriate use of psychoactive medication in medical, neurologic, obstetrical, and surgical conditions.
8. Assessing and managing suicidality and other high-risk behavior in the medical setting.

Adapted from ACGME Program Requirements for Graduate Medical Education in Consultation-Liaison Psychiatry.

ACCESS TO CONSULTATION-LIAISON PSYCHIATRIC CARE: IMPLICATIONS FOR HEALTH POLICY

Despite an abundance of evidence that psychiatric and psychosocial interventions have positive economic and clinical outcomes for patients with co-occurring psychiatric and medical problems, access to and reimbursement for psychiatric and other mental health services are severely limited. In the United States, reimbursement for these services is complex due to the separation of mental health and physical health benefits in most private and public insurance coverage. Even in areas where there is reimbursement for mental health services, it is often administered through a mental health carve-out that separates reimbursement for these services from the medical care reimbursement, resulting in patients not being able to receive care in the medical setting or have access to professionals with the appropriate expertise to treat psychiatric conditions in the context of complex medical illnesses.

Over the past several years, health care reimbursement has been shifting from paying for services delivered (fee for service) to paying for value. Value-based payments range from increasing payment based on provider or health system improvement in outcomes or other measures of quality to putting health systems fully at financial risk for the delivery of care to a population. Given the high cost of care for patients with comorbid mental health and other nonmental health conditions, treatment provided by C-L psychiatrists can help to improve both clinical and economic outcomes. C-L psychiatrists are participating in efforts to define processes of care, including proactive inpatient consultations, depression screening and treatment, use of validated rating scales in treatment of mental disorders in all care settings, and measurement of outcomes of care. These measures can support the roles of psychiatry in the medical setting in value-based care.

ACKNOWLEDGMENT

The founding editor of this textbook, Harold I. Kaplan MD, had a long-standing interest in psychosomatic medicine and the history of psychiatry. He wrote the section on the history of psychosomatic medicine for the first edition of this textbook and for each subsequent edition thereafter until his death in 1998. This chapter includes some of his original work.

27.2 Cardiovascular Disorders

JUDITH RESTREPO, M.D., MARGO C. FUNK, M.D., M.A., F.A.C.L.P., AND SCOTT BEACH, M.D.

Cardiovascular disorders are the leading cause of death in the United States and the industrialized world. Coronary artery disease (CAD) is one of the leading causes of worldwide disability burden. Psychiatric disorders are widely associated with cardiovascular disease, both in the development of cardiovascular disease itself and as a complication. Comorbidity poses a treatment challenge for cardiology and psychiatry. Behavioral risk factors, such as smoking, sedentary lifestyle, and failure to adhere to medical treatment recommendations are clearly exacerbated by psychological stress and psychiatric illness. Moreover, psychiatric disorders are common in many cardiac patients, and intervention not only improves adherence to and outcomes of medical therapy but also relieves suffering due to the psychiatric illnesses themselves. From an epidemiologic standpoint, the most important categories of cardiovascular disease include CAD, heart failure (HF), arrhythmias, and valvular and myocardial disease. This chapter provides a brief presentation of background information on these cardiovascular conditions and is accompanied by a discussion of psychological conditions and psychiatric disorders as risk factors for their development and course. The chapter also includes some discussion of the cardiac impacts of psychopharmacology and other conditions of interest before turning to psychiatric comorbidity with established cardiovascular disease and relevant treatment issues.

CAD AND HTN

Brief Review of Symptoms Treatment and Epidemiology

Atherosclerotic CAD is a progressive physiologic process characterized by the formation of atherosclerotic plaque in one or more of the coronary arteries, which then can have progressive effects on the heart. Acute episodes of illness occur owing to the formation of thrombus on the surface of a disrupted atherosclerotic plaque, leading to total or subtotal occlusion of the affected coronary artery, abrupt myocardial ischemia, and, if not rapidly corrected, myocardial cell death. These acute coronary syndromes (ACS)—unstable angina, myocardial infarction (MI), and cardiac arrest—lead to death or progressive disability due to recurrent pain, cardiac arrhythmias, and HF. Approximately 18.2 million adults older than 20 years of age in the United States have CAD, making it the most common type of heart disease. In the United States, the incidence of CAD is more than 5 million cases per year, and more than 600,000 persons per year have a first MI. Established risk factors for CAD include family history, male sex, hypertension (HTN), hyperlipidemia (HLD), diabetes (DM), sedentary lifestyle, obesity, and smoking. Premenopausal women have reduced risk compared to men, but the incidence of clinically significant disease rises after menopause to match that of men. Atherosclerosis generally begins early in life but is not clinically evident until midadult life. Behavioral and psychological factors have increasingly been recognized to contribute to the risk of incident CAD and disease progression. Notably, depression is independently associated with an almost doubled risk of the development of CAD. Current practice in the treatment of ACS attempts urgent thrombolysis or revascularization by a percutaneous coronary intervention (PCI) procedure (angioplasty, stent placement, atherectomy) or coronary artery bypass graft (CABG) surgery. Preventive measures and medical management include β-adrenergic blockade; statin therapy to stabilize plaque; and aspirin or antiplatelet drugs, exercise, abstinence from or cessation of smoking, blood pressure control, and maintenance of normoglycemia. Complications of acute or progressive disease, such as arrhythmias and HF, must also be treated.

Role of Depression, Anxiety, and Post-Traumatic Stress Disorder

Depression, anxiety, post-traumatic stress disorder (PTSD), and acute and chronic mental stress have been evaluated as risk factors for the development and progression of CAD. Structural impacts of mental health such as low socioeconomic status and low social support have been shown to have significant relationships with each of these individual psychological factors, and some investigators have proposed these latter characteristics as more promising indices of psychological risk. Data from the Normative Aging Study demonstrate a dose–response relationship between negative emotions (a combination of anxiety and depression symptoms) and incident CAD.

Depression. Depression is strongly associated with an increased risk for the development and progression of CAD. Numerous large-scale, prospective, epidemiologic studies reflect an increased relative risk of first MI and cardiac-related mortality in those with depression. This finding holds even after controlling for smoking, a potent risk factor for cardiovascular morbidity and mortality. Smoking as an additive risk remains far more prevalent in those with depression than in the population at large. The effect of depression on risk for MI remains in follow-up over 10 to 20 years. Meta-analyses have also demonstrated patients with pre-existing CAD and depression have doubled risk of adverse coronary disease–related outcomes, including MI, revascularization procedures for unstable angina, and death, as compared to nondepressed counterparts. Depression also has been shown to more strongly predict reduced perceived quality of life (QOL) and physical functioning than physiologic cardiac limitations such as reduced ejection fraction or exercise-induced myocardial ischemia. A widely replicated relationship appears to exist between the severity of depression symptoms after acute MI or unstable angina and the risk of death over a 5-year follow-up, even after controlling for other significant prognostic factors (Fig. 27.2–1). Depression is also associated with an increased risk of death at 5 and 10 years of follow-up as related to the intervention of CABG, including immediately prior to or at 6 months postintervention. In addition, poor response to antidepressant treatment after an MI is associated with a higher risk of subsequent cardiac events and death.

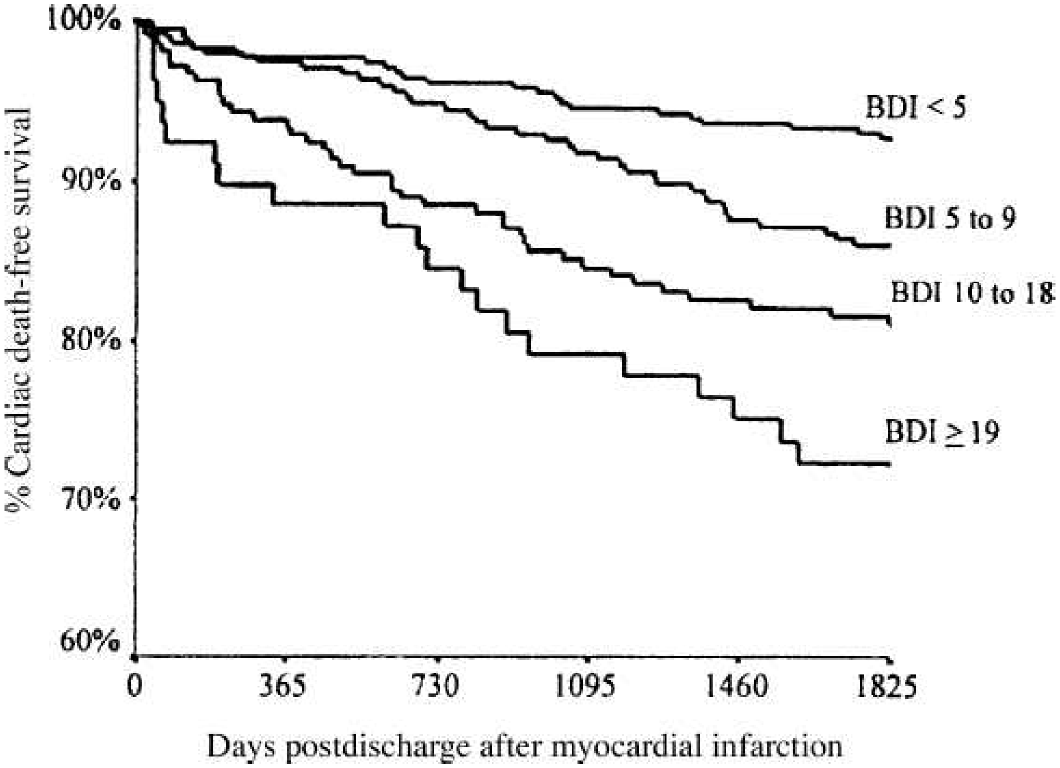

FIGURE 27.2–1. Long-term survival after myocardial infarction in relation to Beck Depression Index (BDI) score during hospitalization. (Reprinted with permission from Lespérance F, Frasure-Smith N, Talajic M, Bourassa MG. Five-year risk of cardiac mortality in relation to initial severity and one-year changes in depression symptoms after myocardial infarction. *Circulation*. 2002;105(9):1049.)

The mechanisms by which depression may increase coronary disease risk have not been established, but potential mechanisms may be organized into behavioral and biologic pathways. Behavioral mechanisms include social isolation, physical inactivity, poor adherence, and smoking. The relationship between cigarette smoking and mental illness, particularly depression, has been well documented. History of depression is associated with a lifetime risk of smoking, current smoking, and a lower successful quit rate. As the prevalence of smoking trends downward in the United States, these associations have strengthened.

Biologic pathways include links of depression with abnormal neuroendocrine and autonomic function, smoking, and platelet dysfunction. Hypothalamic–pituitary–adrenal axis dysregulation in depression is manifest by elevated levels of circulating cortisol and loss of the usual diurnal variation in cortisol level. Elevated cortisol has toxic effects on the coronary artery endothelium and plays a role in plaque development. Disordered platelet aggregation, leading to increased thrombus formation, may also play a role in increasing the risk of coronary events in depression. Measures of in vivo platelet activation and platelet aggregation show that depressed patients exhibit greater prothrombotic activity at baseline and greater platelet activation by an orthostatic challenge. Serotonergic antidepressants, especially those with a high affinity for the serotonin reuptake transporter, reduce platelet activation, and several studies indicate that they reduce the likelihood of first MI.

Anxiety Disorders and Post-Traumatic Stress Disorder. Anxiety is common in those with CAD. The estimated 12-month prevalence of any anxiety disorder in those diagnosed with CAD is estimated to be over 10% in men and almost 25% in women. Most studies have focused on the role of depression as an independent risk for the development of CAD; however, anxiety has also been shown to independently impact the prognosis of those with CAD outside of depression. Panic disorder, in particular, has been associated with CAD. Anxiety has been associated with the progression of pre-existing CAD. Studies have demonstrated a specific increase in the risk of cardiac death in those with unmanaged anxiety. Like depression, the behavioral impact of anxiety remains a major consideration as a mechanism for its impact on CAD. Anxiety, like depression, is associated with smoking and a sedentary lifestyle. Given the correlation between depression and anxiety, it is difficult to fully differentiate the impacts of anxiety in isolation without more longitudinal and large population studies. Less data are available regarding whether treatment of anxiety is beneficial in impacting the incidence and progression of cardiac disease.

The impact of PTSD on the development and course of cardiovascular and cerebrovascular disease has become a topic of considerable recent investigation. Military combat veterans with PTSD have an increased risk of the development of CAD, HF, and peripheral vascular and cerebrovascular disease. The estimated prevalence of PTSD in those with CAD has varied from 4% to 24%. PTSD has been induced by cardiac disease and its interventions at a prevalence rate estimated to be 12% on average. The effects remain significant after adjustment for smoking, depression, and other CAD risk factors. Both behavioral and physiologic processes are likely to be involved as mediators of risk of CAD, including smoking, difficulty adhering to a healthy lifestyle, and autonomic dysfunction with abnormal sympathetic nervous system activation. Even after adjustment for medication adherence, PTSD is associated with increased morbidity and mortality as related to cardiac disease.

Stress and Behavioral Risk Factors

The focus of study regarding correlations of stress and CAD has largely been related to the impact of stress on blood pressure, given the clear link of HTN to the development of CAD. Laboratory and ambulatory monitoring studies clearly demonstrate that acute mental stress results in transient elevation of systolic and diastolic blood pressure. Some studies have found that these transient hemodynamic responses predict increased blood pressure and incident HTN over long-term follow-up. Some population-based cohort studies, examining stress, negative affect, and anxiety as predictors of incident HTN, have found a positive association, with 1.5- to 3-fold increased risk, while others have found none or even a negative association.

HTN is an asymptomatic chronic condition that eventually results from and is highly associated with the risk of CAD, other vascular diseases and their complications, MI, and cardiomyopathy. In the United States, 20% to 50% of adults have a diagnosis of HTN. Epidemiologic risk factors for the development of HTN include male sex, family history, non-White race, and high dietary sodium intake. The role of psychosocial risk factors in the development of HTN is controversial. Anxiety, acute mental stress, chronic anger, and job strain have been associated with the risk of HTN; however, epidemiologic studies have not yielded consistent associations.

Acute mental stress induces arterial endothelial dysfunction and paradoxical vasoconstriction in atherosclerotic arterial segments. Acute mental stress has a significant effect on coronary artery blood flow that may be of significance in patients with pre-existing CAD. States of fear, excitement, and, especially, acute anger reduce blood flow through atherosclerotic coronary segments, provoke coronary spasm, and are associated with abnormal left ventricular wall motion and electrocardiogram (ECG) evidence of myocardial ischemia. Mental stress–induced ischemia is associated with an increased risk of subsequent cardiac events in patients with known CAD and may occur even in patients who do not demonstrate evidence of ischemia during exercise stress testing. Relaxation training can alter autonomic activation during mental stress, and a potential therapeutic role for such training may exist in stress-induced ischemia. There is also evidence that sertraline (Zoloft) treatment reduces myocardial ischemia induced by mental stress.

Studies also suggest chronic mental or emotional stress may also play a role in the development and progression of CAD. Longitudinal community-based studies have found that those who reported persistently difficult close social relationships or reported job strain had an independent elevated risk of new-onset CAD or recurrent cardiac events. In the largest case-control study of predictors of MI, the INTERHEART study found that psychosocial factors, defined as a combination of stress and depression, ranked as the third-highest predictor of MI, raising the risk of MI to comparable levels of smoking or DM. Almost half of adults under 75 report experiencing daily interpersonal stress, which has a substantial impact on health behaviors and mental and physical health. For example, caring for an older adult parent is associated with increased tobacco use, increased alcohol consumption, and sedentary behavior, all of which are risk factors for CAD. A meta-analysis found that subjects who have greater feelings of loneliness and social isolation have a greater risk of new-onset CAD. The INTERHEART study found that, compared to healthy controls, those suffering a first MI self-reported greater stress at the workplace in the prior year. Unemployment and involuntary job loss also have been associated with a nearly twofold increase in rates of both stroke and MI, along with HF. The substantial impact of stress on health is also likely due to major effects on health behaviors, including weight gain, decreased physical activity, decreased sleep time, eating fewer healthy foods, and utilizing increased negative coping behaviors such as alcohol or tobacco use. However, studies of those with CAD found that, even after adjustment for health behaviors, low social support was associated with increased mortality, suggesting that health behaviors may not explain this relationship entirely.

Psychosomatic cardiology research in the 1970s and 1980s was dominated by interest in the relationship between coronary heart disease and a behavior pattern characterized by easily aroused anger, impatience, aggression, competitive striving, and time urgency (the “type A personality”). In the setting of evolving research, hostility is associated with several physiologic processes such as increased circulating catecholamines, increased coronary calcification, and increased lipid levels during an interpersonal conflict. Such processes could, in theory, contribute to CAD when such emotional states are frequent and chronic; however, data remains mixed. More recent attention to traits of negative affectivity (tendency to more commonly experience negative emotions) and social inhibition (the tendency to suppress the expression of emotion) often when combined referred to type D personality. This personality type has been associated with an increased rate of depressive symptoms, lack of positive emotions, and a substantially increased risk of cardiac events in patients with CAD. This personality risk has been more steadily replicated in the literature regarding cardiac risk and has been connected to perceived stress and low self-rated QOL.

Impact of Severe Mental Illness

Persons with severe mental illness (SMI) such as bipolar disorder (BPAD), schizophrenia, and schizoaffective disorder (SCAD) on average have a life expectancy that is 10 to 17.5 years shorter than the general population. The risk of mortality is doubled due to CAD. Even when accounting for the higher rate of death by suicide and accidents, CAD remains the leading cause of death in those with SMI accounting for up to one-quarter of deaths. CAD occurs earlier in people with SMI as compared to the general population and is thought to be partly related to the use of antipsychotics. Atypical antipsychotics impact glucose processing and are associated with rapid weight gain that can lead to metabolic syndrome (HTN, HLD, increased abdominal fat, insulin resistance, and hyperglycemia). Though significant limitations are present in obtaining comparative data between different antipsychotics and risk, research has suggested clozapine (Clozaril), and olanzapine (Zyprexa) carry the highest cardiac–metabolic risk while aripiprazole, ziprasidone, and lurasidone carry the lowest. Mood stabilizers such as valproic acid and lithium are also associated with weight gain.

Those with SMI also have higher rates of sedentary behaviors, smoking, medication side effects, and problems with access to medical care. Smoking is highly prevalent in individuals with SMI, which leads to vascular endothelial damage and systemic inflammation. Smoking cessation can improve psychiatric symptoms, QOL, and if quitting occurs by age 50, cut mortality in half. Smoking cessation can also have an impact on antipsychotic levels. Tobacco smoke increases cytochrome

P450 activity which alternate metabolism of antipsychotics, and levels may increase with cessation. Negative symptoms in patients with schizophrenia are associated with physical inactivity that itself raises CAD and is related to poor diet and obesity. Many studies have demonstrated that the use of metformin with atypical agents such as clozapine or olanzapine reduces medication-related weight gain; however, the long-term impact on CAD outcomes is not clear. For patients with BPAD and SCAD, hypomanic and manic episodes are associated with the increased risk of substance use, which in turn increases CAD risk.

The risk of CAD in SMI remains complex, and many physiologic features suggest that SMI and CAD function in parallel. Both are associated with disruptions in the hypothalamic–pituitary–adrenal axis, inflammation, and immune activation. Lipid metabolism in individuals with BPAD is an area of ongoing research into a potential link between the pathophysiology of BPAD and CAD. Though theories exist, these pathways continue to remain elusive, and further investigation is required regarding the physiologic link between CAD and SMI.

It has been noted that patients with SMI who experience an acute MI are less likely than the general population to receive appropriate treatment, including both medications and revascularization procedures. Those with serious mental illness are at 85% higher risk of death related to complications of CAD as compared to a regionally matched general population. Those with SMI are less likely to have a primary care physician and more likely to have difficulty maintaining continuous insurance coverage. Among patients with schizophrenia entering the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, 88% of patients with HLD, 62% of patients with HTN, and 30% of patients with DM were not being treated with medications for these conditions. Baseline assessments for these patients should include a thorough medical history, thyroid testing, fasting plasma glucose, fasting blood lipid panel, baseline ECG, and resting blood pressure.

MYOCARDIAL DISEASE

Heart Failure

Brief Review of Symptoms Treatment and Epidemiology. HF (formally referred to as congestive HF) is a result of many forms of heart disease and represents the most common final pathway toward disability and mortality. More than 6.2 million adults in the United States have HF, and HF was listed on 13.4% of death certificates in 2018. Half a million people develop HF per year in the United States. The leading risk factors for HF include CAD, DM, HTN, MI, and mitral and aortic valve disease.

Shortness of breath, reduced exercise tolerance and peripheral edema are typical symptoms of HF. Downstream effects of hepatic congestion and renal dysfunction lead patients to struggle with oscillation between the extremes of being “too wet” or “too dry,” often resulting in complex and, at times, varying medication regimens based on symptoms. ECG can demonstrate a shift in axis and conduction changes. Echocardiography or cardiopulmonary exercise stress testing can confirm the clinical diagnosis by formally assessing the heart’s ability to contract. Angiography and positron emission tomography may be used to identify patients who will experience improved cardiac function after a revascularization procedure. B-type natriuretic peptide levels can also be used to mark the severity of physiologic derangement in exacerbation.

HF is a progressive condition with an approximately 50% 5-year mortality. Classification schemes for the staging of HF are shown in Table 27.2–1. To some degree, prognosis depends on the possibility of reversing the underlying cause. Some forms of infectious and inflammatory myocarditis are completely reversible. For most patients, however, the course tends to be one of stable or gradually downhill functional status punctuated by acute episodes of fluid overload or cardiac arrhythmia, precipitating hospitalization.

Treatment of HF patients usually includes angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB), β-adrenergic blocking agents, spironolactone, and diuretics. Heart transplantation and left ventricular assist devices (LVADs) are options for refractory cases. Intravenous (IV) inotropic agents that increase the force and rate of heart contraction, such as dobutamine or milrinone, are sometimes prescribed for severely ill patients who would otherwise succumb to low-output states. Many trials of agents with positive inotropic effects have failed to establish a survival benefit. Cardiac arrhythmias are common in patients with HF, often leading to the need for further medication management.

Table 27.2–1.
Heart Failure Classification

New York Heart Association	American Heart Association
Functional classification	Prognostic classification
Class I: Asymptomatic stage	Stage A: Presence of risk factors
Class II: Mild symptoms with moderate exertion	Stage B: Structural heart disease without symptoms
Class III: Mild exertion limited by symptoms	Stage C: Structural heart disease with current symptoms or previous symptoms that have responded to therapy
Class IV: Symptoms at rest	Stage D: Symptoms are refractory to conventional treatment and require assist device, transplant, or palliative care

Psychological Factors Affecting HF. Relatively little attention has been paid to the role of psychological factors in HF. Poor self-care related to depression has been highlighted as a factor in poor outcomes in HF, along with fatigue, denial, lack of knowledge, and impaired cognitive function. Clinically, it appears that adjustment disorders, depression, and anxiety are relatively common problems in this population. Disorders of alertness and cognition occur in patients with hypotension, hyponatremia, hepatic failure, and renal failure secondary to HF. However, symptoms of HF may confound the psychiatric presentation. Dyspnea and orthopnea, for example, may resemble panic, and particularly orthopnea may interfere with sleep. Hopelessness, decreased self-esteem, suicidal ideation, and other cognitive aspects of affective illness are not normally present in HF patients and may help make the distinction. Comorbid depression is associated with higher morbidity and mortality.

DEPRESSION. Depression has been recognized as a risk factor in HF incidence and mortality, and the role of psychological factors in outcome after heart transplantation has been explored. Longitudinal studies of those with HTN have shown patients with high depression symptoms have higher rates of HF development versus patients with low depressive symptoms. Adjusting for demographic and medical variables, depression was associated with an almost threefold increased risk of the development of HF. Several studies have demonstrated the substantial prevalence of depression symptoms in patients with HF and higher rates of mortality when depression is present. Management of depression symptoms with antidepressants or cognitive behavioral therapy (CBT) has not clearly demonstrated an improved prognosis or reduction in mortality in those with HF.

Surgical Management of HF

HEART TRANSPLANT. Heart transplantation is available to between 2,000 and 2,500 patients annually in the United States. It provides approximately 75% 5-year survival for patients with severe HF, who would otherwise have a less than 50% 2-year survival. Candidates for heart transplantation typically experience a series of adaptive challenges as they proceed through the process of evaluation, waiting, perioperative management, postoperative recuperation, and long-term adaptation to life with a transplant. These stages of adaptation typically are accompanied by anxiety, depression, elation, and working through grief. Mood disorders are common in transplant recipients.

Transplant Medication Interactions. Psychiatric disorders can arise post heart transplantation and can include mood disorders, anxiety, PTSD, sleep disorders, and at times cognitive dysfunction. In addition, medications used for immunosuppression, such as chronic steroids or calcineurin inhibitors (cyclosporin or tacrolimus), are associated with depression, anxiety, insomnia and can have cognitive effects themselves. When managing psychiatric concerns after transplantation considering potential immunosuppressant toxicities or side effects is an important aspect of evaluation. In addition, pharmacologic interactions need to be considered when choosing treatment options.

Selective serotonin reuptake inhibitors (SSRIs) are the most widely used psychotropic medication in the heart transplant population and generally have little effect on the CYPSA4 system with limited impact on immunosuppressant interactions. In-vitro studies have suggested sertraline is the least likely to have medication–medication interactions followed by fluoxetine (Prozac) and then citalopram (Celexa). However, some studies have suggested sertraline can affect cyclosporine concentration. When starting a new SSRI, it has been recommended that monitoring should increase in regards to calcineurin inhibitors until a steady dose is reached. Nefazodone (Serzone) should be avoided in the transplant population because of its impact on CYP3A4 and the risk of altering immunosuppressant levels. The serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine (Effexor) has also been proven to have little effect on the CYP3A4 isoenzyme system and is generally considered to have limited interaction with post-transplant regiments. Other SNRIs have limited data and can be used with caution. Tricyclic antidepressants (TCAs) are generally avoided, given the impact they have on cardiac conduction. St. John's wort, an herbal supplement sometimes used to address mood or anxiety, has been associated with altering immunosuppressant levels, suddenly lowering them, and potentially could increase the risk of rejection.

Other psychotropic medications can also have an impact on a heart transplant. Calcineurin inhibitors can amplify the nephrotoxicity of lithium. The risk of QTc prolongation should be considered in patients that require additional antimicrobial management as part of prophylaxis of high-dose immunosuppression. Beyond medication–medication interactions, other impacts should be considered on patient health. Patients on chronic steroids may have an increased impact of weight gain or metabolic syndrome when given agents such as mirtazapine (Remeron) or atypical antipsychotics.

VENTRICULAR ASSIST DEVICES. The number of patients with end-stage HF utilizing mechanical circulatory support (MCS) has dramatically increased, with over 10,000 people in the United States living with an LVAD for treatment of end-stage HF. Implantable LVADs are the most common type of MCS used in patients with HF. LVADs are used to maintain adequate systemic blood flow in three clinical scenarios: as a bridge to transplantation until a transplant organ becomes available; as a bridge to recovery in patients whose ventricular function is expected to improve; and as destination therapy (DT) in patients requiring life-long MCS due to inability to be listed for cardiac transplant.

ELEMENTS OF PSYCHIATRIC EVALUATION FOR TRANSPLANT OR MCS. In most settings, psychiatric comorbidity is a contraindication for heart transplantation due to the limited supply of organs and concern that patients with psychiatric comorbidity may have difficulty with post-transplant adherence. Though LVADs also require complex care, the selection of recipients, in theory, should be less restricted due to the device availability. In 2018, a collaboration between the International Society for Heart and Lung Transplantation, Academy of Psychosomatic Medicine, American Society of Transplantation, International Consortium of Circulatory Assist Clinicians, and the Society for Transplant Social Workers convened an expert writing group to develop a set of consensus recommendations for the psychosocial evaluation of candidates for both adult cardiothoracic transplant and long-term MCS. Primary evaluation domains include risk factors for poor outcomes after transplantation/implantation; factors related to patients' knowledge, understanding, and capacity to engage in decision making; factors specific to patients' personal, social, and environmental resources, and circumstances; and factors specific to patients under consideration for MCS. The latter domain includes evaluation of understanding of basic device operation and device malfunction; evidence of cognitive limitations or physical limitations that may compromise the capacity to operate the device or appropriately respond to device alarms; and safety of the home environment for device operation, including a reliable source of electricity and accessibility by emergency personnel.

An emerging body of evidence has demonstrated that preoperatively assessed psychosocial variables predict not only psychiatric but also medical outcomes after heart transplantation or MCS. Personality disorders, substance abuse disorders, dimensional measures of coping skills and social support, and clinically assessed compliance history have been linked to the increased risk of poor postoperative compliance, rejection episodes, and increased mortality in heart transplants. Depression and PTSD after heart transplantation are associated with heightened mortality. The largest national study to date of psychiatric comorbidity in continuous-flow LVAD recipients reviewed 15,024 patients enrolled in the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) between 2008 and 2017. The prevalence of psychiatric comorbidities was substantially lower than in the general population. The study also found no increased risk of mortality in patients with a history of drug or alcohol abuse, suggesting that a less restrictive selection process may be warranted for MCS.

Implantation of an LVAD introduces a unique and highly accessible means of suicide, as the device can be actively disconnected or passively allowed to run out of battery power. A 2020 French study of 494 patients who were part of the ASSIST-ICD study found a 2% rate of attempted (*n* = 2) or completed (*n* = 8) death by suicide within the 19-month period following LVAD implantation. Suicide means included LVAD driveline disconnection, driveline section, or drug intoxication. Patients that attempted or completed suicide were significantly more likely to be treated with DT or at a center without an LVAD coordinator. Acute inpatient psychiatric treatment for LVAD patients may prove challenging as most psychiatric units do not have staff who are specially trained in the care and management of a patient with an LVAD. In such cases, close collaboration of the multidisciplinary team (psychiatrist, psychologist, social worker, nursing, LVAD coordinator, cardiologist and surgeon, pharmacist, financial navigator, and primary care provider) is essential. For patients with LVADs, it is important to differentiate suicidality from the desire to stop life-saving treatment for end-stage HF due to impaired QOL. LVAD disconnection may be an appropriate choice once a psychiatric evaluation has ruled out the possibility of treatable psychiatric illness and ensuring there is a consensus of the medical team, patient, and patient’s family.

Cardiomyopathies

Takotsubo Syndrome. Takotsubo syndrome (TTS) is an acute and usually reversible cardiac syndrome, first described in Japan in 1990, characterized by transient, often circumferential, ventricular wall motion abnormalities, which when visualized on echocardiography closely resembles the Japanese octopus trap “Tako-Tsubo.” TTS has been known by a variety of names, including *Takotsubo cardiomyopathy, stress-provoked cardiomyopathy, and broken heart syndrome*. TTS represents 2% of patients presenting to the hospital with acute chest pain. In addition to chest pain, TTS typically presents with ECG changes, significant elevation of serum natriuretic peptide, a small troponin elevation, and normal coronary arteries. There is often partial to full recovery of systolic function at 3- to 6-month follow-up.

TTS is often precipitated by significant emotional stress or physical illness, or trauma. The pathophysiology of TTS is incompletely understood; however, catecholamines appear to have a central role in stunning the ventricular myocardium. A predominance of cases occur in postmenopausal women and though there have been some statements in the literature that this may be due to the coping style of women, a more rigorous hypothesis involves the role of estrogen via several protective mechanisms, including as a sympatholytic and a stabilizer of the hypothalamic–pituitary–adrenal stress response. Furthermore, estrogen modulates the expression of myocardial β-adrenoreceptors, which are thought to play a key role in the development of TTS. Removal of estrogen may increase the susceptibility of postmenopausal women both to the catecholamine storm itself and the downstream deleterious effects on the heart.

Treatment of TTS typically involves the addition of antiadrenergic agents. Emotional or psychiatric triggers should be evaluated and treated. There are no discrete guidelines about psychopharmacologic treatment for comorbid psychiatric illness; however, it should be noted that certain antidepressant classes, including SNRIs, bupropion, TCAs, and monoamine oxidase inhibitors (MAOIs), effectively increase norepinephrine. A few cases of TTS in the setting of SNRIs, atomoxetine, and lithium have been reported. TTS has also been described in the setting of electroconvulsive therapy (ECT). There is a paucity of data to guide psychopharmacologic treatment post-TTS; until there is better-guiding data, it is reasonable to avoid medication classes that increase catecholamine levels.

Hypertrophic Cardiomyopathy. Hypertrophic cardiomyopathy (HCM) is an autosomal dominant cardiac condition characterized by hypertrophy of the left ventricle with or without right ventricular hypertrophy, the systolic anterior motion of the mitral valve, left ventricular outflow tract obstruction, mitral regurgitation, diastolic dysfunction, myocardial ischemia, and fibrosis. HCM is the most common cause of sudden nontraumatic death in adolescent competitive athletes and is associated with a 1% average annual risk of sudden cardiac death. The diagnosis of HCM often follows the sudden death of a close relative, prompting genetic testing and cardiac imaging of related family members. People with HCM have a higher prevalence of mood, anxiety, and substance use disorders than the general population. In patients with HCM, heart-focused anxiety, characterized by repeated complaints of chest pain, palpitations, and other somatic sensations with concurrent fears of having a heart attack or dying, is associated with a shorter length of time since diagnosis and younger age.

Clozapine-Associated Myocarditis, Cardiomyopathy, and Cardiotoxicity. Clozapine has been associated with myocarditis, cardiomyopathy, and subclinical cardiotoxicity, typically in patients without premorbid cardiovascular disease or other medical risk factors. Clozapine-associated myocarditis (CAM) presents with dyspnea, palpitations, tachycardia, low to moderate fever, flu-like illness, nausea, dizziness, and occasional chest pain. The etiology of CAM is unclear but may be due to a type 1, IgE-mediated acute hypersensitivity reaction to clozapine. It is best diagnosed through detection of clinical signs and symptoms, ECG changes (ST-segment depression >1 mm or T-wave inversion in ≥ two contiguous leads other than aVR), abnormal cardiac biomarkers, and results of cardiac imaging (e.g., echocardiography and cardiac magnetic resonance imaging). Endomyocardial biopsy is the gold standard in the diagnosis of CAM, but its use is limited due to the invasive nature of the procedure.

Clozapine-associated cardiomyopathy is a disorder of myocardial contractile dysfunction that may present with dyspnea, tachycardia, palpitations, chest pain, and fatigue, though patients may be asymptomatic. Diagnosis is supported by increased serum BNP and defined by echocardiographic evidence of left ventricular ejection fraction (LVEF) <50% or by a 10% reduction of LVEF from baseline.

Subclinical clozapine-associated cardiotoxicity (SCAC) is typically asymptomatic but may present with paroxysmal atrial fibrillation (AF) and mild left ventricular/biventricular functional impairment. Echocardiography and elevation of NT-proBNP are helpful in the diagnosis of SCAC.

There is no specific requirement for ECG monitoring when initiating clozapine. When possible and where resources allow, a conservative approach involving a baseline ECG and a weekly ECG in addition to laboratory monitoring (troponins, C-reactive protein) and vital signs during the first 4 weeks of treatment may be considered. Alternatively, a symptom-triggered approach to monitoring may be used if concerning signs and symptoms arise. Regardless of the chosen approach, the absence of cardiac monitoring resources should not preclude treatment with clozapine when the cardiac risk is outweighed by the risk of psychiatric morbidity in high-risk psychiatric populations. In general, a clozapine rechallenge is not advised for patients who experience CAM, clozapine-associated cardiomyopathy, or SCAC.

VALVULAR HEART DISEASE

The relationship between valvular heart disease and psychiatric disorders has been a matter of considerable interest over the past several decades.

Aortic Valve Disease

Aortic stenosis (AS) is a narrowing of the aortic valve that can result in chest pain, dyspnea, presyncope or syncope, fatigue, and palpitations. Treatments for AS include medical management and aortic valve replacement (AVR), either surgical AVR (SAVR) or transcatheter aortic valve implantation (TAVI). Primary indications for AVR, per the 2020 American College of Cardiology (ACC)/American Heart Association (AHA) guideline for the management of patients with valvular heart disease, include severe high-gradient AS with symptoms of exertional dyspnea, HF, angina, syncope, or presyncope; symptomatic patients with low-flow, low-gradient severe AS with reduced LVEF; and asymptomatic patients with severe AS and LVEF <50% or who are undergoing cardiac surgery for other indications. The type of valve prosthesis (mechanical vs. bioprosthetic) chosen is based on multiple factors, including patient age, long-term anticoagulation risk (required with mechanical valves), surgical risk, and patient preferences. Replacement by any modality is considered superior to medical treatment.

Current scoring algorithms used to determine the best modality of valve replacement include the European System for Cardiac Operative Risk Evaluation Score (EuroSCORE) II and the Society of Thoracic Surgeons Predictive Risk of Mortality Score (score ≥8% associated with increased mortality). These algorithms do not include assessments of cognition, depression, or other psychiatric illness or frailty, though depression and anxiety are risk factors for adverse effects after cardiac surgery. A recently developed screening tool, SMARTIE (screening for and managing risk factors in TAVI), which uses the Mini-Cog, PHQ-2, and measures of frailty, found that cognitive deficits were an independent predictor of both postoperative delirium and 30-day mortality. Another study found that measures of frailty, specifically the Clinical Frailty Scale, when combined with traditional risk models, improves the predictive value for mortality after TAVI. A recent analysis from the FRAILTY-AVR study, the first to examine the interplay of depression, frailty, and mortality in patients undergoing TAVI and SAVR, found that depression is often underdiagnosed in this population unless specifically screened. Postprocedural changes in depression modulated the effect of depression on mortality such that patients with preprocedural depression that persisted were at greater risk than patients with preprocedural depression that resolved and in patients with new-onset depression postprocedure.

Infective Endocarditis

Infective endocarditis (IE) is an infection of the heart valves and/or endocardium (lining of the heart) caused by bacteria entering the bloodstream from a variety of sources, including dental procedures, cardiac implantable electronic devices (CIEDs), chronic skin disorders, burns, and injection drug use (IDU). The incidence of injection drug use-related infective endocarditis (IDU-IE) in people who inject drugs is 1.5 to 4 cases per 1,000 years of IDU. Surgical intervention (usually valve repair or replacement) is required in 20% to 40% of IDU-IE patients at the time of first-episode IE. More than half of these patients will require repeat surgical intervention due to ongoing IDU. Types of injected drugs vary regionally, but in general, opioids make up most patients with IDU-IE (67%), followed by methamphetamine (26.3%), bath salts (5.3%), and cocaine (16%), with the remainder unknown.

Optimal management of IDU-IE requires collaboration between cardiology, cardiac surgery, psychiatry/addictions with a dual focus on the infection and the substance use disorder. The ACC/AHA guidelines for the management of patients with valvular heart disease recommend the involvement of addiction specialists to guide treatment in patients with IDU-IE, including the assessment of futility when repeat valve surgery is needed in the case of ongoing IDU. Notably, policies requiring abstinence as a requirement for surgery, including the use of signed contracts, are ineffective, especially during the critical period of acute IE when the management of substance withdrawal may not be prioritized, and patients may present as disengaged in the treatment planning process. For patients with opioid use disorder, medications including buprenorphine, methadone, or naltrexone are a critical element of in-hospital treatment and have been shown to reduce mortality, morbidity, hospital length of stay, and use of illicit drugs.

Other Valvular Heart Disease and Psychiatric Disorder Relationships

Mitral Valve Prolapse. The association between mitral valve prolapse (MVP) and a patient's psychological–emotional state, specifically depression, anxiety, panic, and PTSD, has been disputed for decades. Though most patients with MVP are asymptomatic, a small subset experience dyspnea, palpitations, and fatigue. Due to the overlap of such symptoms with some anxiety disorders, a causal link between MVP and anxiety disorders has been suggested, even in the absence of reliable evidence. Several recent studies have disputed these prior claims, suggesting that MVP is not a determinant of a patient's psychoemotional status. Rather it is the patient's perception of the severity of illness that shapes psychiatric symptoms and QOL. It is essential for physicians to present a reassuring stance when discussing MVP with patients, especially in the accurate description of MVP prognosis and treatment.

Obsessive-Compulsive Disorder and Rheumatic Heart Disease. Acute rheumatic fever and its sequela, rheumatic heart disease (RHD), is a preventable inflammatory condition that results from untreated group A β-hemolytic streptococcal (GAS) infection. In 2015, the global incidence and prevalence of RHD, a condition that poses a high burden in low-income countries and among indigenous and other socioeconomically disadvantaged populations, was >300,000 and 33 million, respectively. RHD has been loosely associated with an increased prevalence of obsessive-compulsive spectrum disorders on the whole, including obsessive-compulsive disorder (OCD), subclinical OCD, tic disorders (including Tourette syndrome), trichotillomania, and body dysmorphic disorder. Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) are characterized by the acute onset of OCD, verbal or motor tics, or cognitive disorders in children with a history of GAS infection. The antineuronal antibodies related to GAS infection cross-react with heart valves through molecular mimicry and are identical in both PANDAS and Sydenham chorea. It has been suggested that a relationship between RHD and PANDAS may be mediated by this mechanism. Cardiologic screening may be considered in patients with PANDAS; however, more studies are needed to improve knowledge of this relationship.

ELECTRICAL CONDUCTION DISEASE

Electrophysiology and ECG Interpretation

There are many texts, papers, and guidebooks available regarding in-depth ECG interpretation. In general, most approaches support following a systematic approach of interpretation that includes assessment of the major components of rate, rhythm, intervals, and axis in varying orders. Interpretation of an ECG should begin with an assessment of the patient and the clinical context. The basics of ECG interpretation are outlined below, with the focus of first gathering basic data from the ECG to then guide the interpretation of the rhythm. This review is certainly not comprehensive and is not meant to teach proficiency in atypical rhythm diagnosis. However, we have included a brief reference and refresher on the major components of ECG interpretation.

Terminology and ECG Basics

Rate. The heart rate (HR) can be calculated by a variety of methods. ECGs are composed of boxes of two different sizes. On the x-axis, the boxes represent time. On the y-axis, the boxes represent amplitude or voltage. When using boxes to denote time, the small boxes are equal to 0.04 seconds, and the large boxes represent 0.2 seconds. A standard ECG measures 10 seconds of the heartbeat. As such, there are 5 small boxes per large box and 50 large boxes per 10 seconds of ECG. Since common convention dictates that HR be measured in beats per minute (bpm), 300 large boxes represent 1 minute on the ECG. The “rate by squares” method for determining HR on ECG consists of counting the number of large boxes between R waves and dividing 300 by this number. Another option to calculate HR from ECG interpretation is the “QRS complexes per ECG” method which is often useful in irregular rhythms. This approach consists of counting the amount of QRS complexes on the standard ECG and multiplying by six because the run time of a standard ECG is 10 seconds.

Bradycardia, defined by an HR of fewer than 60 bpm, may occur in normal subjects, especially trained athletes, but also occurs pathologically with medications, hypothyroidism, cardiac ischemia, degenerative conduction disease, excess vagal tone, and during a variety of electrolyte disturbances. Idiopathic primary sinoatrial node degeneration and pharmacologically induced dysfunction are the most common causes of bradycardia. Symptomatic patients typically present with dizziness or syncope. SSRIs have been associated with minor degrees of bradycardia that can reduce cardiac workload and benefit the diseased heart. Lithium is also associated with bradycardia and has been connected to sinus node dysfunction and prolonged sinus node recovery time. HR in patients on lithium has been shown to be lower at rest as well as with exercise though the specific effect of lithium on HR remains unclear as most studies have not controlled for lithium-induced hypothyroidism or patients being treated with other medications which affect HR. Lithium has also been associated with sinus block and sinus arrest. Atrioventricular (AV) node block has also been associated with lithium therapy, but again studies have not clearly controlled for other causes, including cardiotoxic medication.

Tachycardia is defined by an HR of greater than 100 bpm. Tachycardia itself is often asymptomatic unless marked and can be associated with palpitations, weakness, fatigue, dizziness, and near syncope. Psychotropic medication with antimuscarinic and anticholinergic effects (i.e., all atypical antipsychotics, TCAs, MAOIs, benztropine, diphenhydramine) can cause sinus tachycardia which, in healthy patients without cardiac disease, usually resolves with time. Up to 90% of patients taking clozapine have sinus tachycardia.

Axis. The axis of an ECG represents the net vector of depolarization of the heart. It is useful in diagnosing enlargement, rotation of the heart, infarction, and certain arrhythmias. The normal axis of the heart lies between -30 degrees and 90 degrees. Axis can be determined by looking at two leads specifically: Lead 1 (0 degrees) and aVF (90 degrees). These two leads are chosen because they represent perpendicular vantage points from which the net electrical depolarization of the heart can be deciphered. Axis deviation is most commonly a result of ventricular hypertrophy shifting the position of the heart in the chest. Left axis deviation is more common as it can be seen in patients who have had sustained HTN leading to left ventricle hypertrophy. Right axis deviation is relatively rare as it is typically the result of congenital cardiac abnormalities or right ventricle hypertrophy seen in pulmonary HTN or pulmonary thromboembolism (PTE).

Segments and Intervals. The intervals on an ECG are used to assess the amount of time required for a certain portion of the cardiac cycle to complete and thus are a surrogate for the efficiency of conduction through the electrical system of the heart. Common convention dictates that flat areas of the ECG without a wave in them are known as a “segment,” and those with a wave in them are called “intervals.” An ECG tracing is composed of a P wave which is then followed by the QRS complex, and lastly, a T wave. The different waves are created by electrical activity in the areas of the heart (P = atrial depolarization, QRS = ventricular depolarization, and T = ventricular repolarization). Intervals can be pathologically long or short, and changes in their duration can be clues to localize the lesion causing the conduction abnormality.

The ST segment and T wave correspond to ventricular repolarization within the cardiac cycle. As opposed to depolarization which occurs passively by triggering voltage-gated ion channels, repolarization is an active process that requires adenosine triphosphate. Thus, it is especially susceptible to ischemia and hypoxia. ST elevations are most associated with transmural infarction; however, careful attention to the clinical scenario is critical. Entities associated with ST elevations include STEMI, myocarditis and pericarditis, stress cardiomyopathy, left ventricular aneurysm, hyperkalemia, and early repolarization, among others. T-wave inversions are another electrocardiographic finding which can instill fear due to their association with ischemia. It is also important to note that T-wave changes and ST depressions cannot localize to a vascular territory. The differential diagnosis for T-wave inversions is broad and ranges from benign to medical emergency. This includes ischemia, electrolytic derangements, myocarditis and pericarditis, PTE, subarachnoid hemorrhage, and effect from antipsychotic or lithium toxicity. Other T-wave abnormalities such as flattening can be seen with normal antipsychotic doses and electrolyte changes such as hypokalemia and hypercalcemia. Peaked T waves are seen in electrolyte disturbances such as hyperkalemia; however, hyperacute T-wave peaking is the first electrocardiographic sign of ischemia.

Widening of the QRS complex artificially prolongs the QT interval without prolonging repolarization. There is no standardized method to correct the QT interval for a wide QRS. However, the consensus of the AHA, ACC, and Heart Rhythm Society (HRS), recommends adjustment for both QRS duration as well as HR or the use of an alternative interval, such as the JT. Psychiatrists who frequently treat patients with cardiac disease should be familiar with methods to correct the QT interval for a wide QRS. When performing a risk assessment for torsades de pointes (TdP), the presence of ventricular conduction delay (VCD) or VP should be considered evidence of structural or functional heart disease and trigger a correction of the QT-interval duration for the wide QRS.

Rhythms. Identifying rhythms can be an important tool to understanding the electrical pathway of the heart. Rhythms can be considered narrow or wide and regular or irregular. Narrow rhythms are identified by having a narrow QRS and are, by definition, supraventricular. They are narrow because they follow the normal conductive system of the heart. A wide QRS signifies either a ventricular beat or conduction delay, which is sometimes referred to as “aberrancy” or a bundle branch block (BBB). A QRS is wide when the complex is greater than 100 ms. When the HR is fast, and the QRS is narrow, this is referred to as narrow complex tachycardia. When the HR is fast, and the QRS is wide, this is referred to as a wide complex tachycardia. Table 27.2–2 lists the different narrow and wide complex tachycardias.

A normal sinus rhythm will have a P wave preceding every QRS and a QRS coming after every P wave. A total absence of P waves indicates a lack of an organized electrical activity in the atria (such as that seen in AF) or a rhythm generated from below the AV node (e.g., “junctional” rhythm, which happens when the pacemaker cells proximal to the AV node fail to fire). If there are more P waves than there are QRS complexes, an AV block exists.

Table 27.2–2.
Types of Rhythms with Tachycardia

Regular, narrow complex tachycardias	Sinus tachycardia Atrial flutter Atrioventricular nodal reentrant tachycardia (AVNRT) Atrioventricular reciprocating tachycardia (AVRT)
Irregular narrow complex tachycardias	Atrial fibrillation Multifocal atrial tachycardia (MAT)
Wide complex, regular tachycardias	Monomorphic VT SVT with aberrancy
Irregular, wide complex tachycardias	Polymorphic VT (of which torsades de pointes is an example) Pre-excited AF (AKA AF with aberrancy referring to Atrial fibrillation with an accessory pathway)

AF, atrial fibrillation; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Ventricular Arrhythmia and Sudden Cardiac Death

Malignant ventricular arrhythmias may occur as an electrical accident in individuals with no structural heart disease but more often occur in those with underlying heart disease. Because conduction of myocardial depolarization may be delayed in regions of myocardial tissue damage, regions distal to the affected area may be stimulated to depolarization while adjacent tissue is undergoing repolarization, setting off a premature depolarization of the adjacent tissue that may precipitate ventricular fibrillation.

Lethal ventricular tachyarrhythmias are more likely to occur in the setting of structural heart disease (e.g., after an MI) but also are related to genetic disorders regulating ion channels that control ventricular depolarization and repolarization, such as congenital long QT syndrome and Brugada syndrome. These latter disorders are sometimes clinically silent until “unmasked” by medications including lithium, TCAs, and phenothiazines.

Because autonomic cardiac modulation is profoundly sensitive to acute emotional stress, such as intense anger, fear, or sadness, it is not surprising that acute emotions can stimulate arrhythmias. Instances of sudden cardiac death related to sudden emotional distress have been noted throughout history in all cultures. In community samples, depression, phobic anxiety, and mixed anxiety symptoms increase the risk of sudden cardiac death. After the destruction of the World Trade Center in New York in 2001, patients with implanted defibrillators had sharply increased frequency of ventricular tachycardia (VT) events. In post-MI patients with ventricular ectopy, comorbid depression is associated with significantly increased rates of VT–ventricular fibrillation. The effect of psychotropic drugs on the QT interval and arrhythmia risk is discussed below.

Atrial Fibrillation

AF is the most common cardiac arrhythmia in clinical cardiology practice; it is an irregularly irregular heart rhythm characterized by disorganized depolarization of atrial myocytes. The result is ineffective atrial contraction and rapid HR. The ventricular response can follow, becoming extremely rapid, with palpitations and symptoms of reduced cardiac output. The most common risk factors are older age, male gender, HTN, and valve disease. Cardiac surgery, hyperthyroidism, renal disease, DM, sleep apnea, smoking, alcohol consumption, and psychological stress are also associated with the development of AF. AF is associated with increased morbidity and mortality primarily due to CAD, HF, and stroke. Independent of these factors, it is associated with cognitive impairment and psychological distress. Treatment of AF should be focused on mitigating stroke risk as well as rate or rhythm control using β-blockers, calcium channel blockers, cardioversion, or ablation. Anticoagulation reduces the risk of embolic events but increases the risk of bleeding.

AF is linked with depression, anxiety, and mood disorders, as well as poor QOL. A year-long prospective study of 95 patients with AF monitored emotional states via daily electronic diaries found negative affectivity increased the likelihood of an AF episode two- to fivefold, whereas happiness decreased the likelihood. Successfully treating AF has been shown to improve QOL and reduce depression symptoms. Patients with successful ablation had improvement on major depression inventory scores compared to patients with unsuccessful ablations at long-term follow-up. Using antidepressants in patients with AF to control symptoms of depression and anxiety in an effort to prevent AF has not been well studied. However, some studies have shown other methods of management of anxiety and depression, such as yoga, decrease both asymptomatic and symptomatic AF episodes and improve scores of anxiety, depression, and perceived QOL. Management of depression and anxiety should take into consideration the drug interactions between psychotropic and cardiovascular medications. Notably, antidepressants may impact bleeding risk in those who are anticoagulated, as addressed elsewhere.

Depolarization and Repolarization Abnormalities

Repolarization Abnormalities

TORSADES DE POINTES AND QTC. Over the past decade, considerable attention has been paid to the risk of QT prolongation with certain psychiatric medications. QT prolongation is considered a marker of risk for TdP, a lethal polymorphic VT that can present with sudden cardiac death. Medications that prolong the QT interval via effects at the delayed potassium rectifier current (Ik_r) or its encoding gene (hERG) may increase the risk for TdP. Nonmodifiable risk factors for TdP include female sex (between puberty and menopause), increasing age, congenital or acquired long QT syndrome (caused by genetic abnormalities), personal history of structural or functional cardiac disease, or a family history of sudden cardiac death. Besides certain medications, other modifiable risk factors include acute medical illness (particularly cardiac disease), hepatic or renal impairment, hypokalemia, hypomagnesemia, hypocalcemia, pharmacokinetic drug–drug interactions, and bradycardia.

Approach to QTc with Psychotropic Drugs. The QT interval represents the duration of ventricular depolarization and repolarization. Because the QT decreases as HR increases, it must be corrected for HR (QTc). The most common formula used to derive the QTc is the Bazett formula ($QTc = QT/\sqrt{RR}$), a square-root formula used as the default formula in most ECG machines. While the Bazett formula accurately estimates the QTc when the HR approximates 60 bpm, it tends to undercorrect at lower HRs and overcorrect at higher HRs. The AHA recommends using a linear correction formula, such as the Framingham

($QTc = QT + 0.154[1000 - RR]$) or Hodges ($QTc = QT + 1.75[HR - 60]$) correction formulas. The QTc interval is normally less than 450 ms in women and 430 ms in men. Prolongation of the QTc interval is associated with progressively increasing risk of TdP. The risk of ventricular arrhythmias increases by 1.052^x, where x is every 10 ms above a QTc of 400 ms. The QTc interval is an imperfect index of risk of TdP and sudden cardiac death: some drugs that prolong the QTc interval have never been associated with cases of TdP.

ANTIPSYCHOTICS. As a class, most antipsychotic agents prolong the QTc interval and may therefore increase the risk for TdP. Among first-generation antipsychotics, low-potency phenothiazines such as chlorpromazine (Thorazine) and thioridazine (Mellaril) cause the greatest degree of QTc prolongation. Although haloperidol, particularly the IV formulation, has historically been associated with QTc prolongation, recent evidence suggests that the risk has been exaggerated, and there is actually no evidence suggesting that any form of haloperidol causes greater QTc prolongation than most other antipsychotics. Ten of 11 prospective studies involving >1,500 patients and doses up to 20 mg of IV haloperidol found no evidence of QTc prolongation.

Among second-generation antipsychotics, aripiprazole (Abilify) and lurasidone (Latuda) are the only agents that have not been associated with QTc prolongation, with some evidence suggesting that aripiprazole may even shorten the QTc interval slightly. Ziprasidone (Geodon) is associated with the greatest QTc prolongation of the second-generation antipsychotics, with iloperidone (Fanapt) a close second, though TdP is rare with either. Other atypical antipsychotics, including olanzapine, risperidone (Risperdal), and clozapine, prolong the QTc to some degree but are not thought to convey substantial risk. Notably, quetiapine (Seroquel) does have an additional warning from the U.S. Food and Drug Administration (FDA) regarding the potential for QTc prolongation. It is generally not possible to risk stratify most antipsychotic agents, aside from concluding that thioridazine, ziprasidone, and iloperidone carry increased risk, while aripiprazole and lurasidone carry lower risk. Other agents cannot be separated out from one another.

For patients who do not have heart disease, none of the second-generation antipsychotics has a well-established risk of TdP when taken at recommended doses. If feasible, ECG monitoring should be considered for any patients prescribed thioridazine, ziprasidone, or iloperidone, or for patients with multiple other risk factors for QTc prolongation and TdP being prescribed any antipsychotic agent. For patients in the hospital prescribed IV haloperidol, daily ECG monitoring may only be needed for cumulative doses >25 mg or in patients with multiple risk factors.

An increase of 30 ms should trigger increased monitoring, and an increase of 60 ms is a cause for concern. A particular time patients are at elevated risk for TdP is during a restraint. During this time, there are increased circulating catecholamines increase cardiac oxygen consumption and lower K^+ uptake into the muscle (through adrenergic stimulation), leading to low serum K^+ levels. This metabolic risk, combined with the inherent antipsychotic risk, leads to increased myocardial instability and a high risk for arrhythmia. Other risk factors for drug-induced TdP include older age, female sex, electrolyte abnormalities, renal or hepatic dysfunction, pre-existing heart disease (e.g., infarction), bradycardia, and treatment with more than one QT-prolonging agent as well as genetic predisposition. Table 27.2–3 outlines other substances that have been shown to prolong the QT interval.

ANTIDEPRESSANTS

Serotonin Modifiers. For many years, SSRI antidepressants were largely considered safe with regard to QTc prolongation, though case reports existed for all agents except for paroxetine. In 2011, the FDA issued a warning regarding the risk of QTc prolongation with citalopram, stating that it should not be used at doses greater than 40 mg. This warning was based on a thorough QT study, which demonstrated QTc prolongation of 18.5 ms at 60 mg. Subsequent studies have suggested that citalopram does separate out from other SSRIs and typically causes a dose-dependent QTc prolongation of 10 to 20 ms, though the risk of TdP appears minimal. In the setting of the FDA warning, a large percentage of patients had their doses of citalopram reflexively reduced, leading to increased psychiatric morbidity without impact on cardiac mortality.

Table 27.2–3.
Substances that Prolong the QT Interval

- **Alcohol**
- Amiodarone
- Azithromycin
- Chloroquine
- Cisapride (withdrawn due to TdP)
- Citalopram
- Clarithromycin
- Cocaine
- Disopyramide
- Dofetilide
- Erythromycin
- Fluconazole
- Furosemide
- **Halofantrine**
- Ketoconazole
- Levofloxacin
- Methadone
- Moxifloxacin
- Pentamidine
- Procainamide
- Quinidine
- Quinolones
- Sotalol
- Tamoxifen
- Terfenadine (withdrawn due to TdP)
- Vandetanib

TdP, torsades de pointes.

Escitalopram (Lexapro) has also been shown to separate out from other SSRIs in a few studies, though the associated QTc prolongation is minimal, and no warnings exist for escitalopram. Other SSRIs are generally considered safe, with sertraline having been studied the most in cardiac populations.

Among other antidepressants, venlafaxine has been associated with QTc prolongation in some studies. Mirtazapine also has mixed evidence, with some studies suggesting no risk of QTc prolongation even in overdose, but one study suggesting some association with an increased risk of arrhythmias. Bupropion (Wellbutrin) was associated with QTc prolongation in overdose in one study, but this was likely driven by tachycardia and the use of the Bazett formula to derive the QTc. Other antidepressants, including duloxetine (Cymbalta), have not been associated with QTc prolongation.

Trazodone (Desyrel) exerts a modest dose-dependent prolongation of the QT interval, which is likely clinically insignificant, but warrants caution in cases of overdose. Neither benzodiazepines nor buspirone (Buspar) has an appreciable effect on the QT interval. Multiple cases of QTc prolongation and TdP have been reported with donepezil (Aricept). However, the association is unclear, considering all reports have been in patients older than 80 years with multiple other risk factors for QTc prolongation. Amantadine (Gocovri) has been found to trigger TdP in the setting of overdose and co-ingestion with other QTc prolonging agents.

Based on the available evidence, there is no indication for ECG monitoring in most patients prescribed antidepressants. For patients with significant risk factors, a baseline and follow-up ECG is recommended when feasible. For patients being started on citalopram, even without other risk factors, this may be a reasonable approach as well. It is important to not reflexively reduce a patient's citalopram dose, however, and compelling arguments can be made for the use of citalopram at doses greater than 60 mg in select patients and with judicious monitoring.

Tricyclic Antidepressants. As opposed to SSRI and other antidepressants, which can cause QTc prolongation via effects on repolarization, TCAs have long been known to affect depolarization, leading to QRS widening. The effect is dose dependent but can happen at both therapeutic and toxic doses. The change is unlikely to be clinically relevant in a normal heart. However, complete heart block can occur in the presence of pre-existing BBB, second and higher degrees of AV block, or with toxic levels (i.e., overdose). Ventricular pacemakers may also be suppressed by TCA, causing ventricular asystole. They should therefore be avoided in all cases of conduction disease beyond a first-degree block.

OTHER PSYCHIATRIC MEDICATIONS

Mood Stabilizers. Antiepileptic medications, including valproate (Depakote), lamotrigine (Lamictal), carbamazepine (Tegretol), oxcarbazepine (Trileptal), topiramate (Topamax), and gabapentin (Neurontin), have not been found to prolong the QT interval. Valproate may have some protective effects via stabilization of cardiac conduction. In 2021 the FDA issued a drug safety communication that lamotrigine carries the potential for increased risk of arrhythmia in people with clinically important structural or functional heart disorders. The mechanism of risk was not defined except to warn that risk may be further increased when used in combination with other sodium channel blockers, including carbamazepine and oxcarbazepine (about which the FDA stated should not be considered safer than lamotrigine until more data is available). Notably, sodium channel blockade affects the ventricular *depolarization* phase of cardiac conduction, not the repolarization phase represented by the QT interval.

The effect of lithium on QTc prolongation is uncertain, as only a few small studies have examined the relationship. Serum lithium concentrations within the therapeutic range of 0.6 to 1.2 mEq/L do not appear to prolong the QT interval. There does appear to be a positive correlation between increased serum lithium concentrations and QTc prolongation; however, QTc increases are modest and unlikely to be clinically significant.

Stimulant and Stimulant-Like Medications. No statistically or clinically significant changes in the QT interval have been found in clinical trials of short- and long-term treatment with methylphenidate (Ritalin) and amphetamine drugs. Atomoxetine (Strattera) has been linked to QTc prolongation by a few case studies. However, these were complicated by other variables, including the concurrent use of other QTc prolonging medications. Furthermore, a pooled analysis of five randomized, double-blind trials showed no clinically significant QTc prolongation with atomoxetine. Atomoxetine has been shown to inhibit the IK_r channel in vitro in a dose-dependent fashion, which may have implications for QTc prolongation in cases of overdose. Modafinil has no clinically significant effect on the QT interval. Clonidine and guanfacine have not been associated with statistically or clinically significant increases in the QT interval.

Methadone and Buprenorphine. Methadone has a strong association with QTc prolongation and TdP. Cardiac monitoring recommendations for methadone have been controversial, given competing priorities to sustain a high degree of vigilance through ECG monitoring while maintaining a harm reduction approach that aims not to restrict access to life-saving treatment for opioid use disorder in settings where ECG monitoring is not available. Methadone safety guidelines proposed by the American Pain Society and HRS in 2013 compromised on the recommendation for baseline ECG monitoring, suggesting that practitioners “consider obtaining an ECG prior to methadone initiation in patients known to be at higher risk” for QTc prolongation and TdP. For patients with known risk factors for QTc prolongation, a prior QTc >450 ms, or a history suggestive of prior ventricular arrhythmia, an ECG should be obtained prior to methadone initiation. Alternatives to methadone, such as buprenorphine (Suboxone), should be considered in patients with a baseline QTc between 450 and 500 ms. It is recommended that methadone not be used in patients with a QTc >500 ms. All identified modifiable risk factors should be evaluated and corrected, if possible, prior to methadone initiation. Buprenorphine is a safer alternative to methadone with no known association with QTc prolongation or TdP. Buprenorphine is known to block hERG Ik_r channels; however, it is a hundred times less potent of an inhibitor than methadone.

Impact with Cardiac Medications. The prescribed prevalence of nonpsychotropic medications associated with QTc prolongation or TdP is high. One in five intensive care unit patients is coprescribed two or more QTc prolonging medications. The top nine medications prescribed by the emergency department have effects on the QT interval. In the outpatient setting, a quarter of all prescriptions are associated with QTc prolongation. Commonly used medications that prolong the QT interval include antiarrhythmics, antiemetics, antibiotics (macrolides, fluoroquinolones), antifungals, antivirals, and anticancer medications.

Depolarization Abnormalities

VENTRICULAR CONDUCTION DELAY. VCD refers to impaired electrical conduction through the ventricles due to slowed, cell-to-cell depolarization of the myocardium rather than rapid conduction through the His–Purkinje system. VCD manifests on the ECG as widening of the QRS complex and includes interventricular conduction delay, BBB, and ventricular pacing.

TCAs have long been known to affect depolarization, leading to VCD. At therapeutic doses, these agents only pose a risk for patients with pre-existing cardiac disease, but in overdose, they can lead to arrhythmias even in otherwise healthy individuals. The use of TCAs in the period following acute MI is contraindicated by FDA. Although no guidelines exist for the use of electrocardiographic screening and monitoring when prescribing TCAs, it is standard practice to obtain an ECG before prescribing a TCA to rule out unrecognized VCD or ischemic heart disease, especially in individuals older than 40 years.

Cardiac Implantable Electronic Devices (CIEDs)

CIEDs detect cardiac conduction and, when the need arises, deliver appropriate electrotherapy, whether it be pacing or shocks. The three main types of CIED are permanent pacemakers (PPMs), implanted cardioverter defibrillator (ICD), and cardiac resynchronization therapy (CRT).

Permanent Pacemakers. PPMs are primarily used for the treatment of bradyarrhythmias, with the goal of sustaining an adequate HR for daily activity. Pacemakers are programmed to monitor HR and initiate pacing if certain criteria are met. Typically, PPMs are set to pace when the HR dips below 50 to 60 bpm. With a growing focus on QTc prolongation and psychopharmacology, it is important to understand how PPMs influence the electrophysiology of the heart and how this is translated onto the ECG. With ventricular pacing, instead of the typical rapid conduction from the AV node through the His bundle and bundle branches, the electrical signal originates from the implanted lead and travels from cell to cell through the myocardium. This cell-to-cell transmission is much slower than the intrinsic conduction system, and as a result, the QRS complex is widened. This QRS widening must be addressed for proper QTc interpretation (see ECG interpretation).

Also relevant to PPMs is the concept of overdrive pacing, which can be used to mitigate the risk of TdP in some high-risk patients. There is evidence to support the reduction of early afterdepolarizations, a common trigger of TdP when the heart is paced at rates of 70 bpm and above. In situations where a patient has numerous TdP risk factors, has a CIED, and requires high-risk psychotropic medications, overdrive pacing may be used to bridge the patient through the high-risk period.

Implanted Cardioverter Defibrillators. ICDs provide high-voltage shocks with the goal of terminating VT or ventricular fibrillation (VF), followed by rapid bursts of pacing to keep the patient alive after or in between shocks. Common clinical indications for an ICD include survival from sudden cardiac arrest due to VF, syncope with clinically relevant sustained VT, long QT syndrome with the experience of syncope (presumed TdP), and HF. All ICDs have a backup pacing function, typically set to pace at 30 to 40 bpm.

Idiopathic Lead Migration. Lead migration is a rare complication of CIEDs that occurs when newly implanted leads dislodge and retract into the device pocket. The phenomenon was first described as “twiddler’s syndrome,” a term suggesting purposeful or subconscious manipulation by the patient, observed on chest radiographs by twisting of the leads along the long axis of the pulse generator. Later terms include “reel syndrome” and “ratchet syndrome.” These phenomena have often been attributed to risk factors, including older adult age, compulsive behavior, or psychiatric history. However, a pooled series of 87 case reports demonstrated no correlation of lead migration with manual manipulation, older adult age, obesity, oversized pocket, or psychiatric history. It is important for psychiatrists to be aware of idiopathic lead migration as patients with an unrelated psychiatric diagnosis who experience this phenomenon may be victims of stigma and incorrectly labeled as “device manipulators.”

MASQUERADERS

Cardiac Masqueraders of Psychiatric Illness

Some cardiac conditions may be “masqueraders” of psychiatric illness, either due to prominent symptoms misidentified as anxiety, mood-related, trauma-based, psychosis, or personality disorder, or conversely, the absence of an easily identifiable “medical” cause.

Syncope and Torsades de Pointes Masquerading as Nonepileptic Seizures. The frequency of epilepsy misdiagnosis has been estimated at 20% to 30%. Cardiovascular conditions, most commonly syncope, and nonepileptic seizures are the most common imitators. The reflex syncopes (vasovagal syncope, carotid sinus syncope) may cause blackouts complicated by abnormal movements (myoclonic jerking, convulsions) secondary to generalized cerebral hypoxia. TdP may also present with seizure-like activity and should always be considered in the differential, especially if the patient is prescribed a QTc-prolonging medication.

A comprehensive cardiology workup is suggested in all patients with symptoms suggestive of epilepsy who are not found to have electroencephalogram correlates of typical paroxysmal events. As nonepileptic seizures (neurologic symptom disorder/conversion disorder) are a diagnosis of exclusion, it is imperative for cardiac causes of blackouts, spells, and paroxysms to be ruled out. A study of 1,567 patients receiving formal evaluation at an epilepsy center, including video-EEG, found that of 78 cases not receiving a diagnosis of epilepsy who were referred for additional cardiologic assessment and syncope was formally diagnosed in 50 patients.

Pulmonary Thromboembolism. PTE may present with symptoms of dyspnea, chest pain, cough, anxiety, palpitations/racing heart, fainting, and lightheadedness. Many of these symptoms can also be seen in anxiety disorders and panic attacks, leading to the potential for misdiagnosis of this life-threatening condition. Patients with a premorbid psychiatric diagnosis may be at higher risk for misdiagnosis or delayed diagnosis of PTE due to “diagnostic overshadowing,” a phenomenon that can impair the diagnostician’s ability to look beyond a psychiatric etiology. Risk factors for PTE include malignancy, fractures of the leg or hip, hypercoagulable state or clotting disorder, history of MI or stroke, recent major surgery or travel, obesity, sedentary lifestyle, immobilization, pregnancy, older age, and hormone replacement. PTE should always be considered in the differential of a patient presenting with new-onset anxiety or panic, especially if symptoms are accompanied by hemodynamic changes or if PTE risk factors are present.

Psychiatric Masqueraders of Cardiac Illness

Atypical Chest Pain and Functional Cardiac Symptoms. Somatic symptom disorder, panic disorder, anxiety, PTSD, and depression can all present with somatic complaints and represent a substantial issue in ambulatory and emergency cardiology practice. In studies of patients presenting with the chief complaint of palpitations, these diagnoses account for approximately 30% of cases. In this population, the psychiatric disorder is associated with more frequent recurrent symptoms, emergency room visits, hypochondriacal concerns, and impairment in activities of daily living. Similarly, chest pain is a common presentation for panic disorder. In a study of 1,999 consecutive patients presenting with chest pain, a panic disorder was diagnosed in 38%. Patients without CAD were twice as likely to receive a panic disorder diagnosis. Panic patients were younger, more likely to be female, and more likely to be unemployed. In another study of individuals presenting to the emergency room with noncardiac chest pain (NCCP), variables associated with panic disorder included the absence of CAD, female sex, atypical quality of chest pain, younger age, and high level of self-reported anxiety. Recommendations for patients presenting with NCCP and found to have psychiatric morbidity include CBT, mindfulness-based stress reduction, hypnosis, breathing training and guided physical activity, pharmacotherapy, and care management approaches.

PSYCHIATRIC SYMPTOM MANAGEMENT OF PATIENTS WITH CARDIAC DISEASE

Depression

The mainstay of pharmacotherapy in patients with depression and cardiac disease is the SSRI antidepressants. Sertraline, in particular, has been the most studied agent in cardiac populations and is often considered the first-line agent. In patients with ACS, the sertraline antidepressant heart attack randomized trial (SADHART) demonstrated that sertraline was a safe and effective treatment for major depression, indistinguishable from placebo with respect to hemodynamic, ECG, and inotropic effects. Sertraline was associated with a higher rate of response to treatment, better QOL, and a trend toward fewer adverse cardiac events. The antidepressant effect was most pronounced in patients with more severe depression, with prior episodes of depression before the index cardiac event, and with the onset of the current episode before the index event. Several other small trials have tended to show a beneficial effect of sertraline on depression after MI. In contrast, however, a randomized placebo-controlled trial of sertraline for depression in HF patients did not show benefit with respect to either cardiovascular or mood outcomes.

The CREATE trial showed that citalopram is effective when combined with clinical management for the treatment of major depression in patients with CAD. However, given emerging concerns with citalopram and QTc prolongation, citalopram is no longer recommended as a first-line agent in patients with cardiac disease. See previous section on repolarization abnormalities for detailed discussion and consideration of QTc impact.

SSRIs inhibit platelet storage of serotonin and may prolong bleeding in patients via an effect on platelets. They do not have a systematic effect on coagulation, as measured by the prothrombin time test, even in patients treated with warfarin (Coumadin). Bleeding risk is increased in patients treated with concomitant SSRIs, antiplatelet agents, and warfarin, as well as those treated with SSRIs and nonsteroidal anti-inflammatory drugs. The use of acid-reducing medications may mitigate the risk of gastrointestinal bleeding in patients on long-term SSRIs. There is about a 1.5- to 2-fold increased risk of hospitalization for bleeding events when SSRIs are combined with antiplatelet agents or warfarin, and an estimated 36 years of treatment are needed to cause one additional hospitalization. The benefit of SSRI therapy likely outweighs this risk in many patients. Additional cardiovascular effects of psychotropic drugs are listed in Table 27.2–4.

Table 27.2–4.
Cardiovascular Effects of Psychotropic Drugs

Agent	Effects
Tricyclic antidepressants	Orthostatic hypotension; delayed cardiac conduction, heart block; type 1A antiarrhythmic effect; ventricular arrhythmias in overdose; tachycardia
Selective serotonin reuptake inhibitors	Bradycardia Citalopram: Dose-related QTc prolongation
Monoamine oxidase inhibitors	Hypotension; peripheral edema
Bupropion (Wellbutrin)	Hypertension
Nefazodone (Serzone), trazodone (Desyrel)	Hypotension
Venlafaxine (Effexor)	Hypertension, especially at doses >300 mg/day
Lithium (Eskalith)	Sinus node dysfunction, including sinus arrest
First-generation antipsychotic agents	QT interval prolongation; torsades de pointes
Second-generation antipsychotic agents—except aripiprazole (Abilify)	QT interval prolongation

TCAs are no longer recommended because of the risk of orthostatic hypotension, cardiac conduction disturbances, and arrhythmias. See previous section Repolarization Abnormalities for details regarding conduction changes in TCAs. Among other antidepressants, mirtazapine has been found to have some benefit in depressed patients with cardiac disease, but metabolic side effects make it a less ideal medication. Experienced psychiatrists often use stimulants as (off-label) primary or adjunctive treatment of medically ill patients with depressed mood and psychomotor retardation. Please see the attention-deficit hyperactivity disorder (ADHD) section below for information about stimulant use.

Few studies have systematically controlled concurrent treatment and cardiac diagnoses in assessing effects of ECT in cardiac patients, but available information suggests that patients with cardiac disease are more likely than comparison patients without heart disease to experience cardiovascular complications during ECT. During ECT, initial vagally mediated bradycardia is followed by substantial increases in HR and blood pressure. Patients with ischemic heart disease or ventricular arrhythmias are at increased risk of MI or ventricular tachyarrhythmias. Most complications are transient and do not necessarily preclude the use of this modality. ECT has been used successfully in patients with heart transplants.
